Primary amnion (epithelial)			88			100	65		

All the heteroploid cells here used were epithelioid (see Table 1). Small numbers of the heteroploid cells were superinoculated on to a formed monolayer of diploid cells.

\* For example, proteins in diploid monolayer, 800 mg; proteins of heteroploid, 1,600 mg; proteins of combined culture, 2,200 mg: growth of heteroploid in mixed culture,  $\frac{1,400}{1,600}$  88 per cent of that in control. This calculation assumes that the cells in the diploid monolayer were unaffected by the superinoculated heteroploid cells. If appreciable numbers were killed, then the amount of heteroploid growth would be correspondingly greater than the values indicated here. The occasional disparities between the values for heteroploid cells based on cloning and on proteins suggest that this may in some experiments indeed have been the case.

† Based on clonable heteroploid cells.

‡ Based on cell counts.

The mutual effects of heteroploid and diploid cells in culture have been investigated a number of times, with somewhat discrepant results. Most work involved species other than man, and many related to cellular movement rather than growth. Abercrombie *et al.*<sup>1-3</sup> observed that the outward movement of cells from mouse sarcoma 37 and Crocker sarcoma 180 explants was not inhibited by contact with cells similarly growing out of normal mouse or chick tissue explants, and suggested that this lack of inhibition could explain the tumorigenicity of these sarcomas *in vivo*. Although Barski and Béléhradek<sup>4</sup> found that the progressive movement of sheets of malignant mouse cells was inhibited when they came into contact with sheets of normal cells, a few "sentinel" cells penetrated into gaps among the normal cells to establish islands of invasive growth. Stoker<sup>5,6a</sup> found that the growth of hamster cells transformed by polyoma virus was inhibited when they were superimposed on a monolayer of normal hamster or mouse cells, and suggested that the discrepancy with Abercrombie's results could be related to the non-metastatic nature of the tumours formed by the polyoma-transformed cells.

In our experiments, human fibroblasts, whether diploid or with minor chromosomal aberrations, and epithelial amnion cells in primary or secondary culture, all showed a marked diminution in growth rate on the formation of a confluent monolayer on a glass surface. In mixed culture, most fibroblast strains similarly and indiscriminately inhibited each other's growth. In contrast, despite the inhibitory self-recognition of amnion cells and fibroblasts, they did not inhibit each other: whatever the "trigger" mechanism which reduces the rate of cellular growth in these confluent fibroblast and epithelial cell cultures, it is apparently initiated only by contact with cells of the same general type. This type-specific "recognition" is reminiscent of the sorting out of mixed cells in suspension to form homotypic clusters<sup>10-15</sup>. Such cohesive association may be an essential preliminary to the inhibition of macromolecular synthesis and growth in confluent surface cultures of euploid human cells, whether fibroblastic or epithelial. Whereas fibroblasts of different tissue origin would presumably adhere to initiate the growth-inhibitory process, there would be no such intimate association of fibroblasts and amnion cells.

The heteroploid epithelial human cells investigated here, whether originally derived from normal or cancer tissues, continued to grow rapidly even after they had formed a confluent monolayer. The juxtaposition of these cells did not initiate growth inhibition, and the limits on growth *in vitro* were set only later, by factors not yet defined. The growth rate of these heteroploid cells was usually either unaffected, or only slightly reduced, by

intimate contact with fully grown cultures of fibroblastic or epithelial diploid cells. Cancer cells with relatively minor chromosomal aberrations behaved like those with a grossly abnormal karyotype in their continuing growth even when surrounded by, and in intimate contact with, other human cells of either the same or unrelated types.

The dense clumps of growth sometimes formed by heteroploid human cells in the midst of a diploid monolayer (Fig. 3) contrast sharply with the limited growth of the surrounding normal cells, and resemble the similar piled-up cell plaques formed in fibroblastic cultures by some virus-transformed cells<sup>16</sup>. The pattern of growth appears analogous to a clump of tumour cells growing in an organ, surrounded by the normal cells from which they arose. Furthermore, there is a similarity between the invasive growth of cancer cells *in vivo*, and the occasional "invasion" of diploid fibroblasts by the uninhibited spreading growth of superinoculated heteroploid cells. Most cultured human cancer cells are heteroploid, and have escaped from contact inhibition of growth; and it is tempting to relate their partial escape from growth controls *in vivo* to that escape from contact inhibition. On this basis, the proximal cause of the malignant transformation would be an alteration in the cell surface in consequence of which it escapes from contact inhibition of growth; and its invasive properties would presumably reflect a similar escape from contact inhibition of move-

Fig. 4. Failure of a diploid fibroblast monolayer (foetal adrenal) to inhibit the growth of superinoculated heteroploid cells (amnion WISH). Human adrenal cells planted were at  $8 \times 10^4/\text{cm}^2$ . After 6 days, when the cells had achieved a confluent monolayer, they were overlaid with WISH cells at  $4 \times 10^4/\text{cm}^2$ . The photograph was taken 6 days later.

ment. The possible growth-regulatory significance of contact inhibition *in vivo* is not excluded by the finding that high concentrations of serum relieved contact inhibition in a spontaneously transformed mouse culture<sup>26</sup>, or that a perfused culture of human embryonic lung cells grew beyond the limits ordinarily posed in cultures fed intermittently<sup>27</sup>. If contact inhibition of growth *in vitro* can sometimes be reversed by methods less drastic than culture subdivision, this lends plausibility to the thesis that it may be a flexible growth-regulatory mechanism *in vivo* as well.

This perhaps simplistic interpretation poses a number of problems. (a) It is by no means certain that intercellular contact is the important growth-regulatory mechanism for normal cells *in vivo*; and if it is not, it would appear unlikely that escape from contact inhibition is the new element which permits cancer cells to grow in the whole animal. (One could make the *ad hoc* assumption of an associative rather than a causal relationship: that the surface change evidenced by escape from contact inhibition of growth *in vitro* is responsible also for the escape from unspecified growth-regulatory mechanisms *in vivo*.) (b) Many heteroploid human cells, as we have shown, originally derived from normal tissue and which arise in culture by "spontaneous" transformation, have also escaped from contact inhibition of growth, yet, unlike cells cultured from human cancers, most of these do not produce tumours on inoculation into, for example, the cheek pouch of the normal hamster<sup>21-23</sup>. (The validity of the latter negative result is, however, debatable in view of the complications introduced by species differences and rejection phenomena. With these human cells there may be no valid test of malignancy short of reinjection into the original donor; the validity even of this could be questioned.) (c) Finally, Stoker<sup>9</sup> has shown that although polyoma-transformed and tumorigenic hamster cells have escaped from contact inhibition of growth, in the sense that they pile up in culture to achieve abnormally high population densities, their growth is inhibited by contact with a fully compacted layer of the parent cell. Qualitatively similar results have been obtained in some (but not all) strains of virus-transformed human cells. There is thus reason to believe that escape from contact inhibition of growth may not be the sole or perhaps even the usual immediate determinant of malignant behaviour *in vivo*.

Escape from contact inhibition of growth *in vitro* is, however, only one of many parameters which distinguish cultured heteroploid cells from their diploid counterparts (Table 7), whether these heteroploid cells derive from cancers, are viral transformants, or have arisen spontaneously. It is true that these changes are not invariable. Thus (a) not all heteroploid cells can be grown in suspension. (b) Similarly, although enhanced cystathionase activity, endowing the cells with the capacity to grow in a cystine-free medium, is a frequent concomitant of chromosomal aberrations<sup>5</sup>, a quasi-diploid (RPMI 2650)

and a hypodiploid (C4) human cancer line which had escaped from contact inhibition of growth, and which had many of the other properties of grossly heteroploid cells, did not show that enhanced capacity to synthesize cystine. (c) Several non-human cells (a mouse fibroblast<sup>24</sup>, a rabbit lens cell (personal communication from A. Shapiro), and several sub-lines of hamster kidney cells<sup>25</sup>) which had transformed spontaneously in culture, with karyotypic and many associated phenotypic changes, continued to show marked contact inhibition of growth, with little or no cell proliferation after the formation of a complete monolayer, and correspondingly low maximum population densities. (d) The appearance of new antigens, a frequent consequence of viral transformation, has not yet been shown to be a regular occurrence in either cancer cells or "spontaneous" transformants, although some examples have been reported. Despite these and other exceptions, the phenotypic changes listed in Table 7 show a high degree of correlation, and some may well be causally related. An altered surface composition or structure in particular may underlie several of the differences regularly observed between human diploid cells and those with an abnormal karyotype.

The working hypothesis remains tenable (see Boveri<sup>28</sup>) that genomic changes of widely varying causation and extent, and frequently evidenced in visible chromosomal aberrations, can sometimes produce phenotypic changes which permit the altered cell to escape from normal control mechanisms *in vivo*, and thus determine the character of malignancy. Whether the specific change is primarily metabolic (analogous to the enhanced cystathionase activity of heteroploid cells), or whether, for example, a surface change leading to escape from contact inhibition of growth is the immediate determinant of the malignant transformation, should perhaps remain an open question.

We thank Miss Mina Levy and Mr. Leonard Cohen for technical assistance. This investigation was supported by a Public Health Research Grant, U.S. National Institute of Allergy and Infectious Diseases, and by grants from the American Cancer Society and the National Science Foundation. One of us (E. M. L.) was a special fellow of the National Cancer Institute.

Table 7. COMMON\* PHENOTYPIC DIFFERENCES BETWEEN PARENT AND "TRANSFORMED" CELLS IN CULTURE

	Parent euploid cells	Transformants "spontaneous" virus-induced carcinogen-induced cancer
Karyotype	Euploid	Aneuploid
Life expectancy	Finite	Immortal
Malignancy	0	+
Plating efficiency	<1%	50%-100%
Surface properties		
Contact inhibition of movement and growth	+	0
Maximum population density/cm <sup>2</sup>		Increased
Growth in suspension	0	+
Arrangement of fibroblasts in packed culture	Ordered	Random
Morphological changes		+
New antigens		+
Biochemical activities		
Alkaline phosphatase		Increased
Cystathionase		Increased

\* Common, but not invariable, in that not all transformants show all the phenotypic changes listed.

## ASTRONOMY

## An Experimental Test of the Mechanism of Radio Emission from Cosmic Ray Showers

THE suggestion by Askaryan<sup>1</sup> that a detectable radio pulse should be emitted by an extensive air shower was based on the coherent emission from a negative charge excess in the shower front. A more detailed analysis by Kahn and Lerche<sup>2</sup> showed that a radio pulse may also be emitted by the transverse current in the shower front which results from separation of charges in the Earth's magnetic field. Using a restricted model of the shower, consisting of a ring of charges, they showed that the radiation resulting from separation of charges would be expected to dominate over that from an excess of charges.

Radiation from separation of charges would be polarized perpendicular to the Earth's magnetic field, while that from an excess of charges would be polarized radially from the shower centre. Measurements of radio polarization have been obtained by Jelley *et al.*<sup>3</sup>, and by Allan and Jones<sup>4</sup>, who found no clear evidence for an east-west polarization, and by Borzhovski *et al.*<sup>5</sup>, who claimed to have found statistical evidence in favour of it.

A further test of the relative importance of the effects of the geomagnetic field and the separation of charges is to compare the magnitudes of pulses radiated by showers travelling along and perpendicular to the Earth's magnetic field. We have therefore compared the radio pulses received in identical aerial systems directed to the north and south at Jodrell Bank, where the dip angle is 68°. The aerials were corner reflectors two wavelengths long, with a beam-width of 45° directed at 45° to the zenith. The receiving equipment and the Geiger-Müller counters used to detect the shower front were similar to those used in the original detection of the radio pulses, except that further counters were added to form seven equilateral triangles extended along an east-west line 175 metres long. This line also contained the aerials, mounted back-to-back 29 m from the centre. Coincidences were registered whenever the three counters of any one triangle were simultaneously struck, and the two receiver outputs were then photographed. About eight coincidences per hour were obtained with this system, which corresponds to a threshold energy of about  $5 \cdot 10^{16}$  eV.

The analysis consisted of recording the pulse heights in a channel centred on the expected position on the oscilloscope time base, with a width corresponding to the measured time jitter of  $\pm 0.5$   $\mu$ sec which resulted from the variable delay in the Geiger-Müller counters. A reference channel 10  $\mu$ sec later was also analysed in the same way. The results of this analysis are presented in Table 1 as the number of pulses in each channel the amplitude of which exceeds one of three specified levels, increasing by 6 decibels in peak power.

We note that there is a consistent excess of large pulses in the two signal channels but that there is no evidence of any difference between the north and the south channels.

Table 1

Level	1	2	3
South signal channel	210	38	2
North signal channel	247	36	1
South signal—south reference	41	17	2
North signal—north reference	43	14	1

Although the statistics are poor, it is already clear that radio pulses arriving across the lines of the geomagnetic field are not usually stronger than those which arrive along them. The expected ratio of the numbers in the lower two rows of Table 1 is about 7:1 if the shower numbers vary as  $\cos^7$  (zenith angle) as recorded by Macleod<sup>6</sup> and the radio pulses wholly arise from the effects of the geomagnetic field. We must therefore conclude that the effects of the separation of charges do not dominate as Kahn and Lerche suggest they do. One possible explanation of this discrepancy between theory and observation is that the showers contain a higher excess of charges than was suggested by Askaryan, consisting, perhaps, of electrons of lower energy than those normally recorded experimentally.

We thank Dr. J. V. Jelley for advice and help and the Atomic Energy Research Establishment, Harwell, for providing the apparatus for the particle detectors.

A Galactic Discontinuity at  $l^{\text{II}} = 140^\circ$ 

THERE is substantial evidence of a major discontinuity in the structure of the Galaxy at  $l^{\text{II}} = 140^\circ$ . This evidence is provided by large changes in the numbers of Wolf-Rayet stars, dust-embedded stars and interstellar globules, in the wavelength dependence of the position angles of interstellar polarization of starlight, and in the orientation of the polarization vectors of galactic radio waves on each side of that longitude.

The Wolf-Rayet stars provided the first evidence of the discontinuity. It was pointed out by Vorontsov-Velyaminov<sup>1</sup>, and confirmed by Roberts<sup>2</sup> and by Stephenson<sup>3</sup>, that the anticentre region from  $l^{\text{II}} = 140^\circ$  to  $l^{\text{II}} = 225^\circ$  is completely devoid of Wolf-Rayet stars (Fig. 1a).

Hoffleit<sup>4</sup> and Blanco and Williams<sup>5</sup> discovered groups of stars in which the brightest are the most heavily reddened, apparently by circumstellar obscuring clouds. A survey by Reddish<sup>6</sup> has shown that such dust-embedded stars occur in a considerable number of associations and very young clusters, but that none of these are in the range of galactic longitudes from  $l^{\text{II}} = 136^\circ$  to  $l^{\text{II}} = 253^\circ$  (Fig. 1b). In addition to this general relationship with the distribution of Wolf-Rayet stars there is a more detailed relationship in that Wolf-Rayet stars are most often found in systems containing dust-embedded stars.

Estimates of the masses of interstellar globules, of the circumstellar clouds around dust-embedded stars, and of the shells around Wolf-Rayet stars, show that the masses are similar and of the same order as those of early type stars<sup>6</sup>.

These observations support the views that massive stars form from globules and that Wolf-Rayet stars are very young objects in the last stages of contraction to the main sequence. They indicate that the region from  $l^{\text{II}} = 140^\circ$  to  $l^{\text{II}} = 250^\circ$  is not at present active in the formation of massive new stars.

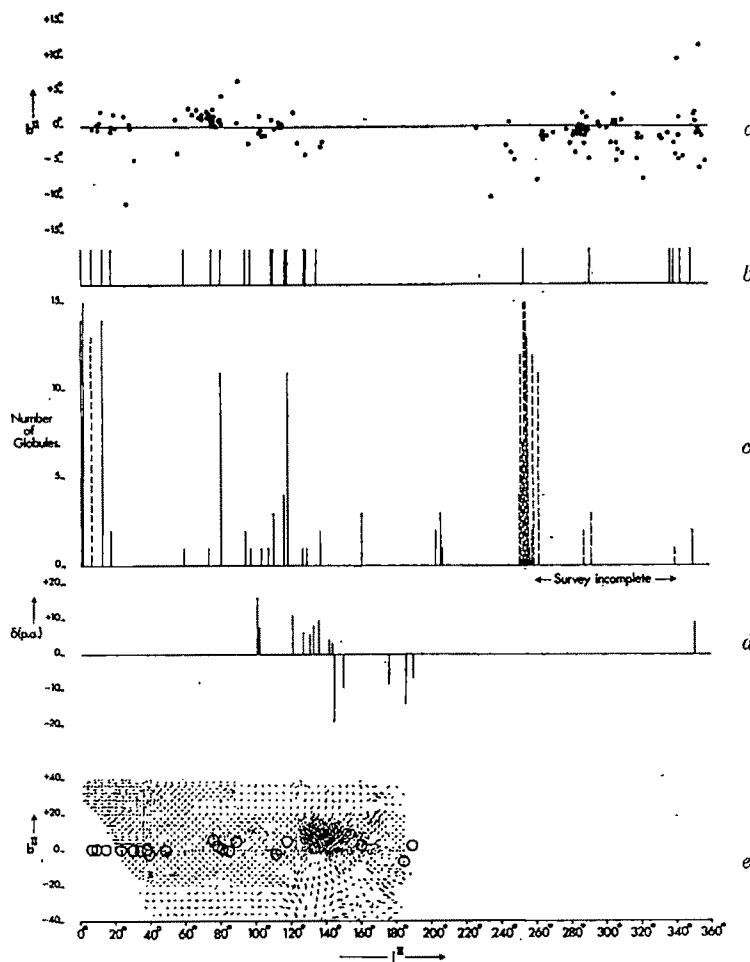

Fig. 1. The distributions with galactic longitude of: *a*, Wolf-Rayet stars; *b*, associations and young clusters containing dust-embedded stars; *c*, globules (broken lines indicate provisional values); *d*, the rotation with wavelength of the p.a. of the polarization vector of starlight, from  $1/\lambda = 3.04\mu^{-1}$  to  $1/\lambda = 1.05\mu^{-1}$ ; *e*, polarization vectors of galactic radio noise at 408  $\mu$ c/s.

The discovery of these relationships indicated that a survey of the distribution of globules in young clusters and associations would be useful. The survey is being carried out by M. E. Sim at the Royal Observatory, Edinburgh, for the sixty-six clusters and associations investigated for dust-embedded stars, and is three-quarters complete. The results show a substantial deficiency in the numbers of globules found in associations and young clusters in the longitude range  $l = 120^\circ$  to  $l = 250^\circ$  (Fig. 1c).

Measurements of the wavelength dependence of the position angles of the interstellar polarization vectors of starlight, reported by Coyne and Gehrels<sup>7</sup>, show a systematic dependence on galactic longitude for about half the stars. With increasing wavelength, the vectors rotate clockwise when  $l < 144^\circ$ , anticlockwise when  $l > 144^\circ$  (Fig. 1d). It has been suggested that the effect may be the result of a longitudinal compression of the spiral arms at the smaller longitudes, and a rarefaction at the greater ones<sup>8</sup>. The possibility that the effect is due to the angle of viewing the spiral arms would seem to be discounted by the coincidence of the longitude of null rotation with the boundary of the zones of deficiency of Wolf-Rayet stars, dust-embedded stars, and globules, which indicate a change in the structure of the spiral arm.

The polarization of the galactic radio noise<sup>9,10</sup> at frequencies of 408 Mc/s and 610 Mc/s is very strong at  $l = 141^\circ$ ,  $b = +6^\circ$ , a region which appears to be the

focal point of a pattern of symmetry in the polarization (Fig. 1e).

A large change in the apparent space densities of Wolf-Rayet stars, dust-embedded stars, and globules, and in the structure of the interstellar medium as indicated by the polarizations of starlight and radio noise, occurs close to  $l = 140^\circ$ . These changes indicate a major discontinuity in the structure of the Galaxy at that longitude. It is possible that a similar discontinuity in the reverse sense occurs at  $l = 250^\circ$ .

## Measurements of OH Emission Sources with an Interferometer of High Resolution

PREVIOUS experiments at Lincoln Laboratories, M.I.T.<sup>1</sup>, California Institute of Technology<sup>2</sup> and Jodrell Bank (to be published) to determine the angular size of the OH emission regions have used interferometers with baselines of about 0.5 km ( $\sim 3,000$  wavelengths). None of the emission sources was resolved which showed that their angular sizes were less than 20 arc secs. Between January 9 and January 27, 1967, measurements were made on a baseline of 127 km ( $7.0 \times 10^5$  wavelengths at 18 cm) in a direction approximately north-south (hour angle,  $353.8^\circ$ ;  $\delta$ ,  $-37.2^\circ$ ). This represents an increase of 200 in resolving power compared with the previous measurements.

The telescopes used were the Mark II at Jodrell Bank and one of the 25 m aerials of the Royal Radar Establishment. Parametric amplifiers gave an overall system noise of about 160° K on each telescope. Both feed systems could be remotely switched to receive left-hand or right-hand circularly polarized radiation. Linear polarization was also measured using oppositely polarized feeds at the two ends of the baseline. The phase stability of the system, although not capable of giving absolute phase measurements, was adequate to give a steady fringe rate over periods of several minutes and consequently the fringe rate was automatically slowed from a natural fringe frequency of about 40/sec to 1/min. Six adjacent 3 kc/s bandwidth filters and a 200 kc/s bandwidth filter centred on the narrow band frequencies were used. The output of the various channels was fed directly into an *Argus* 100 computer which integrated the output over intervals of 4 min.

Observations were made of the features in the 1,665 Mc/s spectra of the OH emission sources near W3, W24-B2, W49 and W75, and in the 1,667 Mc/s spectrum of W49. The positions used for this investigation were those given by Rogers *et al.*<sup>1</sup> and others obtained at Jodrell Bank (to be published). Fringes were observed over a wide range of hour angles for the strong features in all the spectra investigated.

Fringe amplitudes were converted into flux densities by comparison with the fringes obtained from two calibrating sources, 3C 273 B and 3C 454.3. Both these sources are known to be unresolved<sup>3</sup>, and were assumed to have flux densities of  $26.9$  and  $11.5 \times 10^{-26}$  Wm<sup>-2</sup> (c/s)<sup>-1</sup>, respectively. Zero baseline fluxes of the OH spectral features were measured with the Mark II telescope alone and were calibrated by observations of Cassiopeia A ( $2.02 \times 10^{-23}$  Wm<sup>-2</sup> (c/s)<sup>-1</sup>). The fringe visibilities near maximum resolution of the stronger components of the OH sources were found on initial reduction to be greater than 0.6. On

the simplifying assumption that the emission regions have a gaussian brightness distribution the half-power widths of W3, W49 and W75 are less than 0.1 arc seconds. In the case of W24-B2 the maximum projected baseline is smaller and the width is less than 0.2 arc seconds. Final reduction of the data is expected to give more accurate fringe visibilities.

Information on the angular size of the various components can also be derived from observations of fringe amplitude as a function of hour angle. Data for the strong component in the spectrum of W3 at +249 kc/s in right-hand polarization (Institute of Radio Engineers convention) have been reduced in some detail and show a fringe amplitude which does not change by more than 15 per cent between projected baselines of 0.4–1.0 times the maximum. In addition the maximum baseline flux is within 15 per cent of the zero baseline flux. It is thus highly probable that the component is unresolved in all position angles, and has a fringe visibility greater than 0.85. The corresponding diameter of the equivalent gaussian source is less than 0.05 arc seconds.

The linear sizes corresponding to these derived limits of the angular sizes can be calculated from the distances of the HII regions which have been identified with the OH emission sources. Values are given in Table 1. In the case of the nearer OH sources (W3 and W75) the corresponding linear diameters are less than about  $6 \times 10^{-4}$  parsec (pc) and for the more distant OH sources (W24-B2 and W49) the linear diameters are less than about  $10^{-3}$  pc. The upper limit to the diameter of the apparent emitting area of the +249 kc/s right-hand component of W3 is  $5 \times 10^{-4}$  pc which is only about the diameter of the orbit of Pluto.

Lower limits to the equivalent brightness temperatures  $T_B$  of spectral components in the various OH sources can be derived from the measured angular diameters and flux densities. Values are given in Table 1 for the strongest component of each source.  $T_B$  is typically  $> 3 \times 10^9$  °K and for the +249 kc/s right-hand feature of W3 it is  $> 10^{11}$  °K which is a factor of  $5 \times 10^4$  greater than the limits set for this feature in previous experiments.

Further information about the structure of each OH emission source can be deduced from measurements of the relative phases of the spectral components as a function of hour angle. The sources W3, W49 and W75 show significant changes of relative phase between components.

Table 1. DIAMETERS OF COMPONENTS OF OH EMISSION SOURCES

OH source near	Assumed distance (kpc)	Angular diameter ("arc)	Linear diameter (pc)	$T_B$ of strongest component (°K)
W75	1.5	$< 0.1$	$< 7 \times 10^{-4}$	$> 6 \times 10^9$
W3	2	$< 0.05$	$< 5 \times 10^{-4}$	$> 1.0 \times 10^{11}$
W24-B2	10	$< 0.2$	$< 1.0 \times 10^{-3}$	$> 3.5 \times 10^9$
W49	15	$< 0.1$	$< 7 \times 10^{-3}$	$> 1.6 \times 10^{10}$

### W3 RH polarization

Jan. 24, 1967

Fig. 1. 200 kc/s and 3 kc/s bandwidth fringes obtained with right-hand polarization on W3 on January 24, 1967. The 3 kc/s channel is centred on the +249 kc/s right-hand component. The variation in amplitude on the 200 kc/s channel results from the change of relative phase of the various spectral components of W3 as a function of time.

(So far no analysis has been made of W24-B2.) This was also evident on the 200 kc/s bandwidth output which showed changes of amplitude over periods of an hour. The effect is illustrated in Fig. 1, which is a facsimile of a section of the 200 kc/s and 3 kc/s bandwidth analogue records obtained for W3. In this source, for example, it is found that the +255 kc/s left-hand component is displaced 1.4" relative to the +250 kc/s left-hand component. This displacement is thirty times greater than the upper limit of the apparent size of the components. In the case of W49 the two major complexes found at shorter baselines to be separated by 100 arc seconds were clearly discernible by their different fringe rates. Within complex A (R.A. = 19h 07m 50.0s,  $\delta = 09^\circ 01' 12''$ , 1950.0 co-ordinates) the angular separation of the strongest spectral features was found to be about 0.1 arc seconds. The linear separation of the components in W3 and W49A is about 0.01 pc.

From these observations a picture emerges of compact OH emission sources near HII regions with overall dimensions of about  $10^{-2}$  pc. Within these sources narrow spectral components of characteristically high left-hand or right-hand circular polarization are emitted from smaller regions with apparent diameters of less than  $10^{-3}$  pc. Such a source configuration would be consistent with a maser amplification process for the OH emission (see, for example, ref. 4). On the basis of a maser process the observed brightness temperature limits are equivalent to an amplification factor ( $\ln A$ ) greater than twenty which would imply that the emission of a particular frequency component would come from a very small fraction of the volume of the OH region. A narrowing of the emission lines by a factor of more than 5.5 would result from this amplification. If the overall spread of velocity in the spectra of the sources is representative of the width of the unamplified emission, then the ratio of this spread to the width of individual lines (typically 5–40) would be the true narrowing factor. The present data are consistent with these values.

We thank Dr. H. P. Palmer, W. McCutcheon and D. Williams for assistance during the course of this experiment.

## PLANETARY SCIENCE

### Recent Changes in the Magnetic Dipole Moment of the Earth

IN the course of an investigation into magnetic secular variation, a number of spherical harmonic analyses were performed on successive 5 year means of results from eighty magnetic observatories. From the first three spherical harmonic coefficients the moment of the equivalent dipole of the geomagnetic field ( $M$ ) can be deduced in terms of the radius of the Earth ( $a$ ) from the relation  $Ma^{-3} = \{(g_0^0)^2 + (g_1^1)^2 + (h_1^1)^2\}^{\frac{1}{2}}$ .

The same set of observatories was used at each epoch in order to avoid spurious effects due to different conditioning of the equations. Great care was also taken to remove discontinuities at an observatory due to changes of site or standard. In view of these precautions it is considered that the change of moment between epochs is well determined, although no special claim is made for the accuracy of the absolute value.

The results are given in Table 1.

Table 1

Epoch	$Ma^{-3}$ $\gamma$	$\Delta Ma^{-3}$ $\gamma/\text{yr}$
1942-5	31,324	$-7 \pm 1$
1947-5	31,291	$-7 \pm 1$
1952-5	31,257	$-18 \pm 1$
1957-5	31,194	$-17 \pm 1$
1962-5	31,111	

Table 2

Epoch	$Ma^{-3}$ $\gamma$	$\Delta Ma^{-3}$ $\gamma/\text{yr}$
Nagata <sup>1</sup> 1922-1955	—	-12
Nagata <sup>1</sup> 1945-1960	—	-15
Finch and Leaton <sup>2</sup> 1955	31,200	—
Leaton <sup>3</sup> 1955	—	$-11 \pm 1$
Nagata <sup>1</sup> 1955-1960	—	-17
Leaton <sup>4</sup> 1960	—	$-12 \pm 1$
Nagata <sup>1</sup> 1958-1962	—	-16
Hurwitz <i>et al.</i> <sup>5</sup> 1965	30,981	—
Leaton <i>et al.</i> <sup>6</sup> 1965	30,987	$-16 \pm 2$

It is of interest to compare these results with those from other sources (Table 2).

The suggestion by Procopiu<sup>7</sup> and others<sup>8-10</sup> that the dipole moment passed through a minimum some time between 1930 and 1952 has been questioned by Nagata and Rikitake<sup>11</sup> and by Leaton<sup>3</sup>. The figures in Table 1 clearly indicate that the dipole moment continues to decrease, and suggest an increasing rate of decrease. It is tempting to suggest an eventual field reversal within the next few thousand years.

### Rotational Speed of the Upper Atmosphere, from the Orbits of Satellites 1966-51A, B and C

THE rotational speed of the upper atmosphere at heights near that of the perigee of a satellite can in principle<sup>1</sup> be evaluated from the change  $\Delta i$  in the orbital inclination  $i$  of the satellite. If  $\Lambda$  denotes the ratio of the atmospheric angular velocity to the Earth's angular velocity,  $\Delta i$  is given<sup>2</sup>, as a first approximation, by

$$\Delta i \approx 0.007 \Lambda \sin i \Delta T \text{ degrees}$$

where  $\Delta T$  is the change in orbital period, in minutes. In practice the change in inclination,  $\Delta i$ , is often too small to be accurately measurable, and the most accurate values of  $\Lambda$  are likely to be obtained from the orbits for which  $\Delta i$  is largest. We therefore seek orbits which (i) are near-polar and (ii) show a large change in orbital period.

This method of determining atmospheric rotational speed was applied<sup>2,3</sup> to twenty satellites in the years 1958-65, and the results showed that the atmosphere at heights of 200-300 km was on average rotating faster than the Earth: the mean value of  $\Lambda$  was 1.29, with a root mean square scatter of 0.17. These previous values of  $\Lambda$  were averages over the whole lifetime of the satellites, often 2 or 3 years, because the orbital data were not accurate enough to reveal the change in  $i$  over shorter time intervals. Since  $\Lambda$  may vary with time, there is a clear need for more accurate values over shorter time intervals.

Of all the satellites so far launched, those sent into orbit by an *Atlas-Agena* vehicle on June 9, 1966, are potentially the best for determining  $\Lambda$ . In this launch three objects were placed in orbit: 1966-51A, the *Agenda* rocket, with additional payload; and two small satellites, *Secor* 6 (1966-51B) and *ORS* 2 (1966-51C), which both transmitted radio signals for about 3 months. Initially, all three objects were in polar orbits with periods of about 125 min and perigee heights near 190 km. Because the perigee heights were so low, the decrease in period has been rapid: 1966-51A came down on December 3, 1966, and the other two are expected to decay before July 1967.

The orbital data at present available consist of orbital elements determined by the National Aeronautics and Space Administration for 1966-51B and C during the first 3 months of their lives, and U.S. Air Force "five-card elements" for all three satellites. The best values of inclination are the NASA elements for 1966-51C, shown in Fig. 1. The theoretical variation of  $i$  has been calculated by the methods described in ref. 3, and the value of  $\Lambda$  which best fits the observed values has been chosen. The resulting theoretical curve, with  $\Lambda = 1.5$ , is shown in Fig. 1. The decrease in orbital inclination is usually most rapid when perigee is near the equator, and Fig. 1 clearly shows this effect for 1966-51C. Most of the decrease in inclination occurred in August 1966 when perigee was near the sunset line and at latitudes less than 40°. So 1966-51C suggests that  $\Lambda = 1.5 \pm 0.1$  at sunset at heights near 200 km at latitudes less than 40° in August 1966.

The data for the other two satellites, though not in conflict with 1966-51C, are less accurate. Preliminary results are  $\Lambda = 1.1 \pm 0.2$  from 1966-51A, averaged between June and December 1966, and  $\Lambda = 1.2 \pm 0.2$  from 1966-51B,

averaged between June 1966 and February 1967. We hope to derive a better orbit for 1966-51A from the large number of visual observations available; a better value of  $\Lambda$  from 1966-51B should be obtainable after its decay.

The value obtained for 1966-51C is interesting because it refers to a much shorter time interval than any previous determination by this method. Also the high value of  $\Lambda$ , 1.5, which corresponds to a west-to-east wind of over 200 m/sec at the equator, suggests that there is a particularly strong west-to-east wind at about sunset, a conclusion which is consistent with the small number of results from vapour trails at heights near 200 km.

### Stony Meteorites bearing Maskelynite

Its discoverer, Gustav Tschermak, assigned the name "Maskelynite" to an isotropic substance with the chemical composition of plagioclase, which occurred in the Shergotty achondritic stony meteorite<sup>1</sup>. He first regarded this as a new cubic mineral, but later, finding it also in several chondrites and realizing that it formed pseudomorphs after plagioclase, he reinterpreted maskelynite as remelted or otherwise transformed plagioclase glass<sup>2</sup>. Because its amorphous character was not confirmed and no chemical analyses were made of the chondritic variety, however, Tschermak's reassessment of the nature of maskelynite was not universally accepted by meteorite petrographers.

During a reinvestigation of maskelynite-bearing meteorites undertaken at the British Museum (Natural History), London, concentrates of maskelynite were prepared from two achondrites, Shergotty and Zagami, and from the chondrite Château-Renard. Chemical analyses of the two former confirmed their labradoritic composition (both recalculating in terms of feldspar end members to  $Or_2Ab_{48}An_{51}$  molecular per cent), while the latter has the composition of a plagioclase close to the albite-oligoclase boundary ( $Or_5Ab_{88}An_9$ ). Long exposure X-ray powder photographs of all three concentrates possessed no diffraction lines, indicating that maskelynite lacks a crystalline structure. Taken with the textural evidence of pseudomorphism, these new data substantiate Tschermak's final conclusion.

Maskelynite is known in only three achondrites, Shergotty, Zagami and Padvarninkai. The first two stones are closely similar in texture and mineralogy. Each contains two monoclinic pyroxenes, augite and pigeonite, both showing extensive compositional zoning (Fig. 1); and also two opaque oxide minerals, ilmenite and titanite.

Fig. 1. Values of orbital inclination for 1966-51C, with theoretical curve ( $\Lambda = 1.5$ ). ●, Values from NASA bulletins; —, theoretical curve. Numbers on the curve indicate perigee latitude in degrees.

Fig. 1. Pyroxene quadrilateral (portion of a molecular per cent triangular plot of calcium, magnesium and iron) showing compositional trends of (1) pigeonites in Shergotty, (2) augites in Shergotty, (3) pigeonites in Zagami, (4) augites in Zagami, (5) ferrohypersthene in Padvarninkai, (6) subcalcic ferroaugite in Padvarninkai. Based on electron probe microanalyses.

magnetite (averaging 65 molecular per cent ulvöspinel content). A second isotropic substance with refractive index 1.465–1.475, probably silica glass, occurs as a rare constituent in Shergotty but is apparently absent from Zagami. By comparison Padvarninkai differs significantly; it is a brecciated stone<sup>3</sup>, and although texturally similar to Shergotty and Zagami, it lacks titanomagnetite and contains comparatively unzoned ferrohypersthene and subcalcic ferroaugite as its two pyroxenes (see Fig. 1). Furthermore, it retains some untransformed bytownite plagioclase ( $An_{85}$ ) and the refractive index of its maskelynite ( $n=1.571$ ) suggests a bytownitic composition quite different from that of the Shergotty and Zagami maskelynites. Besides extending the known chemical variation in maskelynites to cover the greater part of plagioclase compositional range, these observations reveal that maskelynite occurs in two distinct kinds of achondrite. Padvarninkai is probably best regarded as a brecciated howardite, but Shergotty and Zagami together constitute a unique class.

Plagioclase of albite-oligoclase composition occurs as a product of recrystallization in numerous chondrites<sup>4–6</sup>. In several cases this plagioclase is replaced by isotropic maskelynite, Château-Renard being a well known example. Of thirty-three chondrites bearing maskelynite recognized in the British Museum collection, no fewer than twenty-eight display black veins or brecciation structures, and of the remaining five, four are such small stones that they could be derived from veined or brecciated bodies. In seven chondrites maskelynite is restricted to the vicinity of veins or brecciation zones while plagioclase remains elsewhere. These features suggest a close genetic relationship between vein-brecciation structures and the plagioclase-maskelynite transformation, and since ultra high pressure shock provides the most acceptable explanation for the geometrical and microscopic characteristics of the former<sup>7</sup>, a shock origin for chondritic maskelynite appears highly likely.

In achondritic meteorites there are fundamental difficulties in understanding a purely thermal transformation of plagioclase to maskelynite without eutectic or eutectic-like melting between feldspar and coexisting mafic minerals<sup>8</sup>. The synthesis by shock of maskelynite-like glasses from albite<sup>9</sup> and bytownite<sup>10</sup>, and the reproduction during explosive shock experiments on a gabbro of textural relationships similar to those in Shergotty<sup>10</sup>, strongly support the alternative—a shock origin for maskelynite—in both chondritic and achondritic meteorites. In this respect it is interesting to note that the average refractive indices of the three analysed maskelynites ( $n=1.544$ , 1.540, 1.502 in Shergotty, Zagami and Château-Renard respectively) are significantly higher than those of glasses of the same composition synthesized by fusion at atmospheric pressure, a feature also recorded in the synthetic shock-produced bytownitic maskelynite.

I am grateful to the staff of the Department of Mineralogy, British Museum (Natural History), for their assistance with this investigation, and particularly to Dr. S. J. B. Reed for electron probe analyses.

## THE SOLID STATE

### Ring Configurations in a Random Network Model of Vitreous Silica

The properties of liquids and glasses may, for many purposes, be classed together. Both lack the extensive regularly repeating groups of atoms that characterize crystalline arrays. X-ray diffraction patterns of both, instead of showing the sharp rings or spots associated with crystal structures, show diffuse bands indicating that the type of order existing in them is limited to a short range.

When considering the structures of such irregular aggregates of atoms, they can be very roughly divided into two types, associated and non-associated. The non-associated types comprise atoms the interactions of which are non-directional: the simplest examples of these are the inert gas liquids, the spherical non-polar atoms of which interact with non-saturating and non-directive forces. The structures of these liquids can be derived to a good approximation simply from packing considerations: this has been done very successfully in the work of Bernal<sup>1–3</sup> and Scott<sup>4,5</sup>. A characteristic of this type of liquid, in contrast to the unique co-ordination in the crystal, is the existence of a distribution of co-ordination numbers, to which the thermodynamic properties are related.

In associated liquids, on the other hand, the interactions between the atoms are directional: they form bonds which occur in definite vectorial positions in space, and there is a limit to the number of bonds which can be formed to a molecule. In this type of liquid the directed forces lead to the formation of an extensive set of rings linking up the molecules. Examples of this type of liquid are water which forms hydrogen bonds, and vitreous silica, both of which consist of tetrahedral arrangements of atoms. It has been suggested by Bernal<sup>6</sup> that in the associated liquids and vitreous silica the statistical variation is not in the co-ordination number but in the number of molecules forming rings.

Using a random network model of vitreous silica, the data concerning which have been published previously<sup>7</sup>, an investigation into the distribution of types of rings which occur in the model has been carried out.

In crystals the rings are regularly repetitive and the types of rings in the immediate neighbourhood of each atom are limited. In tridymite and cristobalite, for example, only hexagonal rings of silicon atoms exist, chair-shaped in the case of cristobalite and chair- and boat-shaped in the case of tridymite. In vitreous silica, on the other hand, rings of four, five, six, seven and more silicon atoms may exist.

When looking at a crystal model such as cristobalite or tridymite it is visually obvious which rings form the neighbourhood of a particular atom. In a random network model, however, which consists of complex and highly interconnected sets of rings, the choice of rings is not always obvious. For this reason it was decided initially to look at the most generalized set of rings so that these could be regrouped in various ways later.

One hundred silicon atoms were selected as centres and the number of rings of each type around each silicon centre were computed using the London University Institute of Computer Science Atlas computer. Rings with up to nine silicon members were selected. For the purposes of the count a ring was defined as any closed path of atoms within the model, each atom of which is connected by an oxygen to two and only two other silicons in the path, and in traversing the path each atom is crossed only once. This meant that an arrangement such as that in Fig. 1 would be counted as one six-fold and two five-fold rings.

In a general count of rings, when the acceptable rings are not limited to those containing only closest neighbours the number of  $n$ -fold rings to a centre increases

with the number of members,  $n$ , in the ring: this is shown in Fig. 2.

A more significant way of looking at the rings is to consider the rings which are formed of the close neighbours of each centre. There are a variety of ways in which this could be effected, for example, the ring count could be restricted to those atoms which were within, say, three Si-Si neighbour distances from a particular centre, or one could limit the number of rings to one, two or more rings to a vertex pair. One way of doing this is to consider each of the pairs of vertices of the  $\text{SiO}_4$  tetrahedra in turn and limit the counts of rings to the shortest path connecting the atoms in each of the pairs. This limits the number of rings to a centre to six. The distribution of rings found for a count of this sort is shown in Figs. 3 and 4.

Fig. 3 shows that five-folds predominate, because the average number of rings to a centre is 2.77 for five-folds, 2.27 for six-folds, 0.94 for seven-folds and 0.02 for eight-folds. Fig. 4 shows the way in which the five-, six- and seven-fold rings are distributed among the centres. There

### Carbon Fibre Composites

EFFECTIVE use of any fibres requires that they be incorporated into a matrix that develops the full strength of the fibres. Much attention, rightly enough, has been given to carbon fibres because of their low density and high strengths and elastic moduli. Rolls-Royce, Ltd., have announced a fibre with tensile strength of 250,000 lb./in.<sup>2</sup> and modulus of 60 million<sup>1</sup>. Several U.S. suppliers have fibres commercially available with strengths to 180,000 lb./in.<sup>2</sup> and moduli to 25 million. In time, fibre properties may approach 500,000 lb./in.<sup>2</sup> strength and 90 million modulus. These properties of fibres are very attractive, but it is the composite properties that are of ultimate importance in the use of the fibre.

We have been working with carbon composites for more than a year, and the results show both deficiencies and strong points for these composites. Our matrix has been exclusively epoxy resin with an amine curing agent, and with a vacuum-temperature precleaning of the fibre to remove volatiles and occluded gases before impregnation with resin. An important relationship found so far is the inverse correlation of composite shear strength with fibre modulus; that is, the greater the fibre modulus, the smaller the shear strength. Fig. 1 graphically illustrates these results. We do not yet know why this inverse relationship holds true. We found that the critical surface tension of 68 million modulus fibres was between 44 and 48 dynes/cm. This value, because it is greater than the surface tension of most epoxy resins, should result in

Fig. 1. Carbon fibres composite shear strength versus fibre modulus. Epoxy resin, amine cure.

spontaneous wetting. Observation of the epoxy meniscus with graphite fibres and the spreading of epoxy on bulk graphite confirms this wetting. Other researchers<sup>2</sup> have reported that surface treatments of graphite fibres with nitric acid resulted in a 50 per cent increase in composite shear strength. There is evidence to indicate that this improvement was brought about by improved bonding to acidic sites created by the oxidation. This increased value, to about 6,700 lb./in.<sup>2</sup>, is still far too small to develop the full strength of the fibres. Shear strength is important in a composite because in compressive applications a mode of failure involves shearing the fibre-matrix bond, allowing the then unsupported fibres to buckle. An engineering rule of thumb is that the shear strength should be 75 per cent the compressive yield strength of the matrix to avoid this type of failure. This indicates 15,000 lb./in.<sup>2</sup> shear strength and greater, far more than the values now being attained.

The fatigue resistance of high modulus (low shear strength) composites is relatively untested, but we expect it to be a direct function of the type of test. If the test applies a high shear load, we would expect the composite to fail quickly. We have shown this in one test which involved the twisting of a half ring, imposing high shear and low bending stresses. Samples fail in shear in the first cycle of this test. The same types of samples, however, when exposed to a fatigue test imposing low shear and high tensile or compressive stresses may last much longer. The low modulus fibres in composites give good fatigue life in the half ring twist test—as good as or better than glass. This is further evidence of the good shear bond.

An additional point is that carbonaceous composites seem reasonably resistant to degradation by water. This is in contrast to the first results obtained with glass-epoxy composites, which in the early days of development could be severely degraded by boiling in water. This prompted the whole research effort on glass finishes, which eventually resulted in silanes and others which made the glass-epoxy composites relatively impervious to water. It appears that no such road need be followed with the carbon fibres, at least for water resistance purposes.

Now, as for shear strength of the high modulus graphite composites, that may be another story.

## PHYSICS

### X-ray Diffraction Experiments in Nano-second Time Intervals

DEBYE-SCHERRER X-ray powder patterns are conventionally obtained on photographic emulsions in times of the order of hours. When special techniques are used, the time required can be reduced to minutes or perhaps seconds. In this communication, we report the recording of X-ray powder patterns on photographic emulsions in nanosecond time intervals.

The pulsed X-ray machine used in these experiments was constructed following the principles described by Blumlein<sup>1</sup> and Fitch and Howell<sup>2</sup>. The machine generated a 50 kV, 50 kAmp electron current pulse with a pulse duration of about 20 nsec. The bremsstrahlung obtained with a tungsten anode was 30 mr. per pulse at a distance of 1 m from the anode. The anodes used in the diffraction experiments were made of titanium and iron. Additional details of the construction of this X-ray machine will be published elsewhere.

The feasibility of pulse X-ray diffraction was shown in a Bragg reflexion experiment with a single crystal of lithium fluoride. The 200 reflexion was recorded on 'Eastman KK' emulsion. The titanium  $K\alpha$  radiation from a single pulse of the X-ray source was used. The experimental arrangement and results are shown in Fig. 1. Because the expected decrease in diffracted X-ray intensity in going from the single crystal experiment to a Debye-Scherrer experiment was about three orders of magnitude, it was not clear that a photographic record of the lithium fluoride powder pattern could be obtained. Using a pellet of lithium fluoride powder in the experimental arrangement shown in Fig. 2a, the 220  $K\alpha$  reflexion was, however, clearly evident on the emulsion, as shown in Fig. 2b. The 220  $K\beta$  and 200  $K\alpha$  lines were also recorded, but the 220  $K\beta$  was too weak to show clearly on the film. Additional confirmation of these results was provided by observing the 400 and 222 reflexions from a pellet of sodium chloride with the experimental arrangement already described. The reflexions from larger

Fig. 1. a, Experimental arrangement. b, Recorded Bragg reflexion.

Fig. 2. a, Experimental arrangement. b, Recorded powder pattern.

*d*-spacings were not observed because of absorption by the sample. By using an iron anode and tipping the pellet of lithium fluoride 45° from the vertical, the 220, 311, 222 and 400 reflexions were observed. All these records were made with a single pulse of X-rays lasting about 20 nsec.

Further work is under way to extend the technique to dynamic experiments in which X-ray diffraction information is obtained while the sample is undergoing structural change. The technique could, for example, be used to investigate phase changes in materials during the passage of shock waves.

We would like to acknowledge the technical assistance of Mr. Andre Kusubov and Mr. Donald C. Kumpf in carrying out these experiments. This work was done under the auspices of the U.S. Atomic Energy Commission.

### Stimulated Emission with a Non-dissociated Europium $\beta$ -Dicetonate

EARLIER it was reported that laser action was obtained at 6111 Å with the sodium salt of europium-tetakis benzoyl-acetonate ( $B_4EuNa$ ) (ref. 1). Spectroscopically, this is the best chelate now known for obtaining stimulated emission: its luminescence spectrum presents only one strong very sharp line, namely 6 Å, in solution at 77° K (ref. 2).

Some spectroscopic characteristics of this chelate contrast with those of its organic cation homologues. The part played by the cation is important and raises the problem of the exact origin of the luminescence spectrum observed.

We have investigated the luminescence at 77° K and the conductance at 295° K of fresh\*  $B_4EuNa$  in pure dimethyl formamide (DMF) and in a mixture of DMF and ethanol (1:3) which makes laser action possible. It is assumed that during the fast cooling of the solutions, the equilibrium reached at 295° K does not noticeably change.

In these two solvents, the  $B_4EuNa$  is partially decomposed and this leads to the formation by the *tris*-ligand of an adduct with the solvent:  $B_3Eu$ , DMF. The 5798 Å line of the *tris*-ligand luminescence spectrum enables its concentration to be determined.

The method of calculation has been described by Brecher, Samelson and Lempicki<sup>3</sup> and consists of comparing heights of the  $^5D_0 \rightarrow ^7F_0$  luminescence lines corresponding to the *tris* and *tetakis*-ligand forms. This method was established for the case when only one form of *tetakis* chelate was present. The case of  $B_4EuNa$  is more complex because two *tetakis* forms have to be considered (see later). Close examination of the spectra reveals that besides the 5798 Å line only one other line is observed with  $B_4EuNa$  at 5801 Å (Fig. 1). We conclude that the 5801 Å line is common to both *tetakis* forms. The 5798 Å line obtained with a  $10^{-2}$  molar solution in DMF is nineteen times less intense than that of a solution of  $B_3Eu$  at the same concentration in the same solvent. In the mixture of DMF and ethanol, this line is only 4.4 times less intense. From these values it can be deduced that there are 7 per cent of  $B_3Eu$  in DMF and 30 per cent in the mixture of DMF and ethanol.

The results of conductance measurements given in Table 1 show that the dissociation of  $B_4EuNa$  is much less than for the other chelates. The considerable decomposi-

Table 1. MOLAR CONDUCTANCE AT 295° K

	$C = 10^{-2}$ moles/l. DMF	$C = 10^{-2}$ moles/l. DMF + EtOH	$C = 2 \times 10^{-3}$ moles/l. Acetonitrile
$BNa$	10	19	20
$B_3Eu$	1.8		
$B_4EuNa$	15.8	10.2	24
$(BTF)_3EuNa$	29.3		103
$B_3EuP$	8.5		47.5
$(BTF)_3EuP$	29.3		119

tion into the *tris*-ligand form<sup>3</sup> explains the low conductance of  $B_4EuP$ . It should be noted that the compound  $BNa$  is clearly not totally dissociated in these solvents.

Considering the size of the  $B_4Eu^-$  ion and the high dielectric coefficient of the solvents, the existence of ion pairs is very improbable. Thus the presence of a molecular form in the solution is demonstrated.

By observing modifications in the relative heights of the  $^5D_0 \rightarrow ^7F_2$  luminescence lines as one passes from one solvent to the other, it is possible to classify the chief lines into several groups within each of which there is a constant intensity ratio (Table 2). The 6111 Å line can be attributed to the molecular form because: (1) it also exists in crystallized  $B_4EuNa$ ; (2) it does not appear in benzoyl-trifluoroacetate which is known to be largely dissociated<sup>5</sup>; and (3) it is greatly diminished in the solution of  $B_4EuNa$  in N-ethylacetamide which has a very high dielectric constant ( $\epsilon = 135$  at 20° C). In the last case, two strong lines similar to those appearing with the dissociated fluorinated chelates are observed at 6122 Å and 6132 Å.

Table 2. CHARACTERISTIC MAXIMA AND SHOULDERS (IN BRACKETS) OF THE LUMINESCENCE OF  $B_4EuNa$  SOLUTIONS AT 77° K (IN Å)

Line group	$^5D_0 \rightarrow ^7F_2$	$^5D_0 \rightarrow ^7F_0$	Attribution
1	6111-6142-6160	5801	$B_4EuNa$ (molecular)
2	(6115)-6135	5801	$B_3Eu^-$
3	(6122)-6177	5798	$B_3Eu$ , DMF

By combining results of conductance and luminescence it is possible to calculate approximately the proportion of each of the three luminescent species  $B_4EuNa$ ,  $B_3Eu^-$  and  $B_3Eu$ , DMF which are in equilibrium.

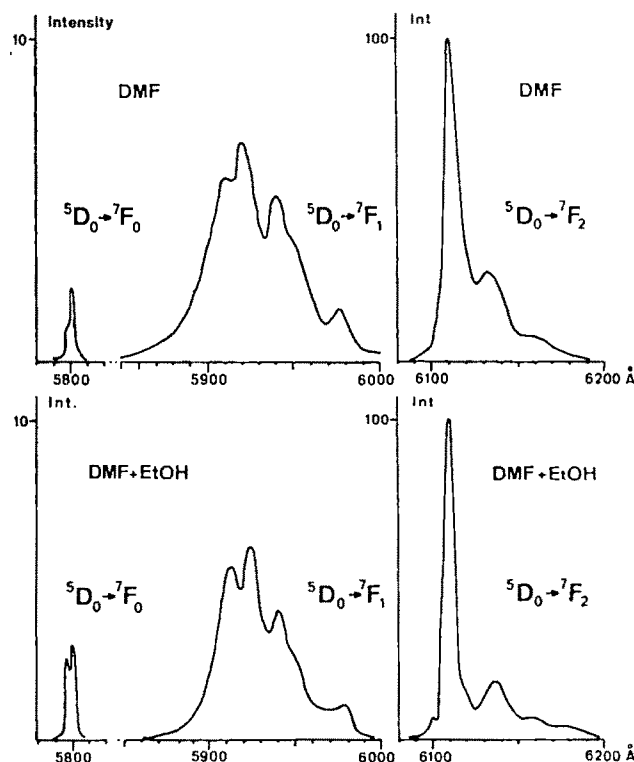

Fig. 1. Fluorescence spectra of 0.01 molar solutions of  $B_4EuNa$  at 77° K (uncorrected for the photomultiplier spectral sensitivity).

\* The solutions are unstable and vary at room temperature. Within a few weeks, the ligands break: B → acetophenone + ethyl acetate (ref. 4).

**DMF solvent.** The limiting ionic conductance of  $\text{Na}^+$  and of a few anions in DMF is known<sup>7</sup>. For anions (which are not solvated in DMF) it is approximately proportional to the reciprocal cube root of the ion mass (if anions have similar densities). This calculation gives, for the limiting molar conductance  $\Lambda_0 = 55 \Omega^{-1} \text{ mole}^{-1} \text{ cm}^2$  for  $\text{B}_4\text{EuNa}$  and 73 for  $\text{BNa}$ . The Onsager equation<sup>8</sup> for the monovalent weak electrolyte is

$$\Lambda = \left[ \Lambda_0 - \left( \frac{82}{(\epsilon T)^{1/2} \eta} + \frac{8.28 \times 10^5}{(\epsilon T)^{3/2}} \Lambda_0 \right) (\alpha C)^{1/2} \right] \alpha$$

where  $\Lambda$  is the molar conductance,  $\epsilon$  is the dielectric constant,  $T$  is the absolute temperature,  $\eta$  is the viscosity,  $\alpha$  is the degree of dissociation and  $C$  is the total concentration. This equation makes it possible to calculate the concentration of the  $\text{B}_4\text{Eu}^-$  ion. The conductance due to  $\text{B}^-$  can be neglected.

**DMF + ethanol solvent.** No data have been published concerning the conductances in the mixture of DMF and ethanol, but it is likely that the ion solvation is identical and that the product  $\Lambda_0 \eta$  (limiting molar conductance and viscosity) is the same in both solvents. The measurement with sodium perchlorate gives  $\Lambda_0 = 54$ . We then deduce that  $\Lambda_0 = 48$  for  $\text{BNa}$  and  $\Lambda_0 = 36$  for  $\text{B}_4\text{EuNa}$ . Here the conductance of  $\text{B}^-$  can no longer be neglected. From a plot of the molar conductance against concentration and from the Onsager equation, it is possible to calculate the ionic dissociation constant of  $\text{BNa}$ .

Moreover, to the first approximation, the conductance  $\chi$  of a  $\text{B}_4\text{EuNa}$  solution is the sum of the conductances due to the two species which can be dissociated

$$\chi = \chi_{\text{BNa}} + \chi_{\text{B}_4\text{EuNa}}$$

$$\text{With } \chi = \frac{C\Lambda}{1000}, \text{ we have:}$$

$$C\Lambda = \Lambda_{\text{BNa}} \cdot C_{\text{B}^-} + \Lambda_{\text{B}_4\text{EuNa}} \cdot C_{\text{B}_4\text{Eu}^-}$$

where  $C_{\text{B}^-}$  and  $C_{\text{B}_4\text{Eu}^-}$  are the concentrations of dissociated fractions and  $C$  the total concentration of  $\text{B}_4\text{EuNa}$ .

$\Lambda_{\text{BNa}}$  and  $\Lambda_{\text{B}_4\text{EuNa}}$  are expressed in terms of the corresponding  $\Lambda_0$  by means of the Onsager equation. It is possible to calculate approximately the concentration of the different species by means of the constant  $K = \frac{C_{\text{B}^-} \cdot C_{\text{Na}^+}}{C_{\text{BNa}}}$  and the equation  $C_{\text{B}_4\text{Eu}} = C_{\text{BNa}} + C_{\text{B}^-}$ , where

$C_{\text{B}_4\text{Eu}}$  and  $C_{\text{BNa}}$  are the respective concentrations (Table 3).

The results are in agreement with the increase of the intensity ratio of the 6111 Å and 6135 Å fluorescent lines going from DMF to the mixture of DMF and ethanol. From Table 3, it can be seen that the concentration ratio  $\frac{C_{\text{B}_4\text{EuNa}}}{C_{\text{B}_4\text{Eu}^-}}$  passes from  $\frac{60}{33}$  to  $\frac{53}{17}$ , that is, a factor of 1.7. On the spectra, direct reading of the intensity ratio of the 6111 Å and 6135 Å lines gives 1.5. Considering the approximations used, the agreement is satisfactory.

With benzoyltrifluoro-acetonates in acetonitrile, however, only the ionic form  $(\text{BTF})_4\text{Eu}^-$  is obtained<sup>5</sup>. Recently, T. M. Shepherd<sup>6</sup> has shown that, in a low  $\epsilon$  solvent like benzene, a different spectrum is obtained, dominated by an intense 6111 Å line. This he attributes to an ion pair. We have verified that the same results are obtained with the  $(\text{BTF})_4\text{EuNa}$  in acetonitrile and in benzene. Thus the  $\text{B}_4\text{EuNa}$  appears to be a particular case in which the sodium is much more strongly bonded.

Table 3. APPROXIMATE NUMBER OF MOLES OF EACH SPECIES WHEN 100  $\text{B}_4\text{EuNa}$  MOLES ARE DISSOLVED.

	$\text{B}_4\text{Eu}$ , DMF	$\text{B}_4\text{Eu}^-$	$\text{B}_4\text{EuNa}$	$\text{BNa}$	$\text{Na}^+$	$\text{B}^-$
DMF	7	33	60	6.5	33.5	0.5
DMF + EtOH	30	17	53	19	28	11

Total concentration of europium was  $10^{-2}$  moles/l.

With  $\text{B}_4\text{EuNa}$ , laser thresholds of only 160 J were obtained at  $-150^\circ \text{C}$ , despite the presence in the solution of a considerable quantity of inactive species absorbing a large part of the excitation which is thus lost for stimulated emission, unless transfer, not yet demonstrated, occurs. We consider that this molecular form is of particular interest for obtaining laser action.

### Comparison of Flow Birefringence Data of Polymers by means of Reduced Variables

Flow birefringence is usually characterized by the variation of the extinction angle  $\chi$  and the birefringence  $\Delta n$  as a function of the velocity gradient  $q$ . This holds in particular for flowing polymer systems, including the limiting cases of very dilute solutions and of bulk polymers in the molten state. In principle,  $q$  can always be eliminated from the two relationships. Although information is lost in this way, the over-riding advantage is that, for small  $q$ , the flow birefringence of polymer systems behaves very much like stress birefringence of rubber-like materials. Such a consideration eliminates the picture of flow, because birefringence is considered as a function only of the stresses.

Let a Cartesian co-ordinate system be chosen with one axis parallel to the direction of laminar shear flow, and a second along the direction of the (constant) velocity gradient and the third axis completes the set. In this co-ordinate system the stress-optical relations read

$$\Delta n \cos 2\chi = C(p_{11} - p_{22}) \quad (1)$$

$$\Delta n \sin 2\chi = C 2p_{12} \quad (2)$$

where  $p_{12}$  denotes the shear stress measured at a plane parallel with the flow direction,  $p_{11}$  and  $p_{22}$  denote normal stresses and  $C$  is the stress-optical coefficient.

It is important to realize that, according to the theory of rubber elasticity, any stress component can be made dimensionless by dividing it by the number of chain molecules per unit of volume times  $kT$ . Applying this principle to equations (1) and (2), the following dimensionless quantities are obtained:

$$E = \frac{\Delta n \cos 2\chi}{3C} \frac{M}{cRT} \quad (3)$$

$$\beta = \frac{\Delta n \sin 2\chi}{2C} \frac{M}{cRT} \quad (4)$$

where  $M$  is the molecular weight,  $c$  is the concentration (that is, the density for the bulk polymer),  $R$  is the gas constant and  $T$  is the absolute temperature. In equation (3) the factor 3 is incorporated. This has been done to give quantity  $E$  the approximate meaning of chain expansion by the following definition<sup>1</sup>:

$$E = \bar{h}^2 / \bar{h}_0^2 - 1 \quad (5)$$

where  $\bar{h}^2$  is the mean square end-to-end distance of the polymer chain during flow and  $\bar{h}_0^2$  is the same quantity at rest.  $\beta$  is very much the same as the well known Bueche-Harding parameter<sup>2</sup>, because  $C$  must be determined by comparison of viscosity and flow birefringence measurements using equation (2)<sup>3,4</sup>.

Dilute solution theory is in accordance with the given quasi-static treatment<sup>5,6</sup>. The same holds for the theory of networks containing cross-links of finite lifetimes<sup>7</sup>. The given reduction (equations (3) and (4)), however, is only meaningful so long as one can speak of separate macromolecules. The same holds for any relationship between  $E$  and  $\beta$ . From Zimm's theory for dilute solution, perfectly flexible macromolecules at low values of  $q$ , Peterlin has shown that

$$E = \epsilon \beta^2 \quad (6)$$

with  $\epsilon$  between 0.136 for impermeable coils and 0.267 for freely draining coils<sup>8</sup>. In actual fact,  $\epsilon$  can take these values only in the case of linear polymers of very narrow molecular weight distribution. For other linear materials  $\epsilon$  should, according to dilute solution theory, rapidly increase with the broadness of the distribution<sup>1,8</sup>.

In Fig. 1 a plot according to equation (6) is presented on a double logarithmic scale. The data were obtained from a series of anionic polystyrenes of different molecular weights. The high molecular weight samples were investigated in monobromo-benzene as a solvent and at a temperature of 25° C (ref. 9). The sample of the lowest molecular weights was investigated in bulk at a temperature of 196° C (ref. 10). The purpose of this graph is to show that the proposed reduction covers pronounced differences in molecular weight, concentration and temperature. Apparently it is valid even for the melt. For  $\epsilon$ , a value of 0.27 is obtained. This is practically within the limits given previously.

It can be concluded from this rather surprising result that even in the melt the polymer molecules behave like separate molecules. The interaction with the neighbour molecules seems to be satisfactorily described by an effective friction factor. The value of this factor is irrelevant when the normal stresses are related to the shear stress.

The coincidence of reduced results shown here is, however, not always found. Concentrated solutions apparently show a more complicated behaviour than dilute solutions or melts, and their  $E$ -values are comparatively higher at corresponding  $\beta$ -values. The results shown in Fig. 1 were obtained for polymer samples which possess a very narrow distribution of molecular weights. With broader distributions coincidence is sometimes obtained for results on dilute solutions and on the melt.

Fig. 1. Double logarithmic plot of the reduced flow birefringence data, obtained on various anionic polystyrenes. The molecular weights are indicated in the graph. Solutions in monobromo-benzene were measured at 25° C, melt measurements were carried out at 196° C.

This matter will be an important point for future investigations. In fact, some theories<sup>11</sup> for the determination of molecular weight distributions are based on the concept of the effective friction factor and on the simple additivity of the contributions of each molecular species to the properties of the bulk.

### A Moving Body must "appear" Cool

LANDSBERG has recently suggested<sup>1</sup> replacing Einstein's law  $T_{lab} = T_{cm} (1 - w^2/c^2)^{1/2}$  with the law  $T_{lab} = T_{cm}$ , where  $T_{lab}$  is the temperature of a body as measured in laboratory co-ordinates,  $T_{cm}$  is the temperature of the body measured in its rest frame, and  $w$  is the velocity of the body relative to the laboratory. The word "appear" was placed in quotation marks in the title because  $T_{lab}$  may not be the temperature as observed by the casual laboratory observer at all, just as the Lorentz contraction is not seen by a laboratory observer under ordinary visual inspection, no matter how large it is, but is replaced by a rotation<sup>2</sup>. A black body at some temperature  $T_{cm}$  will emit a black body spectrum appropriate to  $T_{cm}$  in its rest frame, which will be seen Doppler-shifted to another temperature by other observers. An observer in front will see a blue-shift and one behind will see a red-shift, in neither case by a factor  $(1 - w^2/c^2)^{1/2}$ .

To see what is the proper definition of  $T_{lab}$  one may proceed either via general principles as Einstein did, or via simple hypothetical experiments. The elegance and generality of the former technique evidently are compensated by some vagueness or appearance of arbitrariness, as evidenced by the fact of Landsberg's objection. Thus a simple experiment is desired. It is impossible, however, to carry on the sort of quasi-static variations and transfers of energy demanded by "thermodynamics" (sometimes called "thermostatistics") between two bodies that are moving rapidly together or apart. The only relevant experiment is one where the relative velocity is transverse to the line of centres of the two objects; then the distance remains constant. Consideration of such a hypothetical experiment leads at once to the conclusion that Einstein's definition is the only one consistent with the zero'th and second laws of thermodynamics. [By the zero'th law is meant that there exists a unique function, called temperature (or a one-to-one function thereof), such that two bodies in thermal contact remain in their initial states if and only if they have the same temperature.]

Consider, then, the following experiment: place a black body  $B_1$  at one temperature  $T_0$  at the centre of a revolving turntable, and place another  $B_2$  at laboratory temperature  $T_{lab}$  on the rim, so as to move with constant velocity  $w$ . Allow radiative transfer between the two through a narrow radial tube. Unless the spectrum radiated by  $B_2$  as seen at  $B_1$  is a black body spectrum of temperature  $T_0$ , and that of  $B_1$  as seen at  $B_2$  is a similar spectrum of temperature  $T_{cm}$ , net radiative transfer will occur, causing one to get hotter and the other cooler. Thus one must define  $T_{lab} = T_0$  when the above spectral conditions hold, and only then. Any other definition leads to a viola-

tion of the second law of thermodynamics. But photons from  $B_2$  suffer a transverse Doppler shift toward the red by a factor  $(1 - w^2/c^2)^{1/2}$  as seen at  $B_1$ . Thus  $T_{\text{cm}}(1 - w^2/c^2)^{1/2} = T_{\text{lab}}$ . For consistency, one should verify that photons from  $B_1$  are seen blue-shifted by the factor  $(1 - w^2/c^2)^{-1/2}$  as seen at  $B_2$ . The transverse Doppler shift formula may not be used directly to find out how things are seen by  $B_2$  as it is in accelerated motion, but one may use either of two arguments to solve the problem. First, one may note that the shift already found is because clocks at  $B_2$  would run slower than those at  $B_1$  by a factor  $(1 - w^2/c^2)^{1/2}$ ; applying this in reverse, one finds the proper blue-shift of  $B_1$ 's spectrum as seen at  $B_2$ . Second, one can replace the special-relativistic discussion by one that depends on the equivalence principle, and use rotating co-ordinates in which  $B_2$  is still. Then the spectral shifts are gravitational in origin, because of the gravitational potential  $-\frac{1}{2} r^2 \omega^2$ .

This ensures reciprocity between the spectral shifts of each body as seen at the other. These shifts have been verified in the laboratory<sup>3</sup>, which verifies Einstein's law.

Landsberg's concern about the properties of bodies initially at rest and put into motion does not seem to fall within the scope of this discussion. The results depend on how they are set moving; does one keep the proper volume or the volume as seen in the laboratory constant during the acceleration? Furthermore, deformations must occur, since rigid bodies cannot accelerate, according to the special theory of relativity<sup>4</sup>. The transformation of temperature under consideration is valid only for different observers looking at the same body, or for finding  $T_{\text{lab}}$  for bodies the rest-temperature of which is known by other means, such as by knowledge of their volume, pressure and composition.

## Temperature of a Moving Body

RECENTLY Landsberg<sup>1</sup> suggested that the "true" value of the temperature of a body moving at relativistic speeds will appear the same as the temperature measured by an observer moving with the body itself. This conclusion is reached by re-defining temperature in terms of entropy and internal energy.

Fremlin<sup>2</sup> suggests that some physical concept of temperature must be introduced before the mathematics becomes valid, and shows that if the temperature is defined on a kinetic model (that is relating the temperature to the random velocities of the molecules) then the body appears cooler to any observer relative to whom it has a uniform velocity. He states that the apparent component of velocity in the direction of motion is reduced by a factor  $\beta^2$ , where as usual

$$\beta = \left(1 - \frac{V^2}{c^2}\right)^{-1/2}$$

and  $V$  the velocity of the whole body relative to the observer, while the velocity components perpendicular to the direction of motion are reduced by a factor  $\beta$ .

The apparent reductions in the velocity components are, however, greater than those that Fremlin has calculated. Let the body have speed  $V$  relative to an observer  $A$ . If an observer at rest relative to the body,  $B$ , measures the velocity component of an average molecule in the direction

of relative motion as  $u$ , then the observer  $A$  measures this speed as

$$u' = \frac{u + V}{1 + \frac{uV}{c^2}}$$

(See, for example, McCrea<sup>3</sup> for a derivation of this.)

As the body has velocity  $V$ , observer  $A$  estimates the molecule speed relative to the body as

$$\frac{u + V}{1 + \frac{uV}{c^2}} - V = \frac{u}{\beta^2 \left(1 + \frac{uV}{c^2}\right)} \quad (1)$$

This expression reduces the apparent speed by the further factor

$$\left(1 + \frac{uV}{c^2}\right)$$

over what Fremlin obtained.

A velocity component  $v$  in a direction perpendicular to the motion of the body, as measured by  $B$ , is measured by  $A$  as

$$\frac{v}{\beta \left(1 + \frac{uV}{c^2}\right)} \quad (2)$$

This again is smaller than the Fremlin result by the same factor

$$\left(1 + \frac{uV}{c^2}\right)$$

Thus if the temperature is defined in terms of the random velocities of molecules, the temperature of a moving body will appear cooler. The amount of apparent cooling is, however, greater than deduced by Fremlin, though for most temperature ranges expressions (1) and (2) will reduce to those obtained by Fremlin as  $u$  will be much less than the velocity of light  $c$ .

## CHEMISTRY

### Hydrazine Synthesis in the Silent Electrical Discharge

THE synthesis of hydrazine from ammonia in the silent discharge was first reported by Besson<sup>1</sup>. Subsequent investigations by other workers on flowing systems<sup>2,3</sup> only led to both low conversion and very low hydrazine yields being obtained. The yields are normally expressed as grams of hydrazine per kilowatt hour of energy dissipated in the actual discharge. More recent work claims substantially increased yields by withdrawal from the discharge of the desired product in an absorbent<sup>4</sup>. A reasonable working explanation for the increase in yield reported in this case could well be as follows. The reactions in the discharge are undoubtedly of a very complex nature probably consisting of a series of competing formation and degradation reactions for any particular species in the discharge. The use of an absorbent is equivalent to reducing the residence time of the chemical species in the discharge, that is, it reduces the possibility of its decomposition by either further electron bombardment or other collision phenomena. Ideally, the absorbent would be selective only for the product and allow the activation reactions to take place virtually unhindered by its presence. Furthermore, if the effect of the absorbent is assumed to be entirely physical in nature, it follows that any method of reducing the residence time of the product

in the discharge would be expected to enhance yields. Other possible methods of achieving this same end are increased flow rate, pulsing of the discharge or removal of product by condensation, adsorption or chemical combination.

In order to determine whether such a mechanism is taking place, the hydrazine synthesis from ammonia has been studied in a concentric barrier discharge reactor using several of the suggested techniques for reducing the product residence time in the discharge. Provisional results are given in Figs. 1 and 2, where it can be seen first that yield increased considerably with decreasing residence time in the discharge. Actually, the results could not be extended into the more interesting region of very low residence times because of the pumping limitations set by the experimental apparatus used. This forcibly brought to notice the obvious economic limitation of this method of increasing yield which is dictated by the inherent pumping charges. One obvious way of avoiding this economic difficulty is to use a smaller discharge area. The yields were found to fall markedly with such changes in geometry, however, because of the increased influence of edge effects on the discharge characteristics. The problem could undoubtedly be partly overcome by use of venturi or centrifugal flow acceleration, but further perseverance with this method of reducing residence time in the discharge even with these modifications is not justified if the low percentage conversions are considered.

The use of an absorbent liquid (ethylene glycol) gives markedly increased yields (see Fig. 2). Endeavours to increase the yield still further by providing more intimate spray contact between the absorbent and discharge were not successful because of the dissimilar discharge geometries used for the two types of reactors. The spray reactor would have been expected to give slightly better yields over that of the film reactor. While the discharge gap distances were about the same in each reactor, however, the film reactor was of an annular design and the spray reactor was a wire in a concentric barrier. Thus, the geometry of the spray reactor resulted in the discharge intensity being higher in the centre of the discharge gap. As yield is inversely proportional to this parameter the spray reactor yields were a little lower than those of the film reactor with its more uniform discharge. Other modifications of the technique could be applied which would increase the absorbent discharge exchange, but the results appear to be only marginal.

Despite the use of the liquid absorbent the yield continues to increase with reduction in residence time (Fig. 1). This shows that there is still an appreciable quantity of hydrazine not being extracted by the absorbent. It seems more logical, therefore, to modify the discharge to ensure that hydrazine once formed is not degraded by

Fig. 1. The effect of residence time on hydrazine synthesis from ammonia in a silent electrical discharge. Operating pressure,  $P$ , 40 mm;  $\pi$ , discharge intensity kW/c.c.;  $x'$ , per cent conversion g hydrazine/g ammonia.

Fig. 2. The effect of liquid absorbent and discharge pulsing on hydrazine synthesis from ammonia in a silent electrical discharge. Operating pressure a.c. barrier reactor,  $P$ , 40 mm; d.c. pulsed discharge reactor  $P$ , 10 mm;  $x'$ , per cent conversion g hydrazine/g ammonia.

further electron bombardment which, incidentally, constitutes a waste in power<sup>4,5</sup>. A d.c. pulsed discharge with a variable on-period was used. Results (Fig. 2) show that the yield is increased considerably and that as the on-period is shortened the yield rises and becomes independent of power. It is therefore better to operate at the highest power possible as this will lead to a higher overall conversion from ammonia to hydrazine.

The best yield obtained so far with the d.c. pulsed discharge is about 15 g/kWh or 12.5 g/d. for a power charge of 1.2 d./kWh. As the economic price for large scale hydrazine manufacture and usage is close to this yield the silent electrical discharge route for its synthesis, even at this stage, looks promising. Further refinement of the pulsing technique is obviously required before the process becomes a commercial possibility, but from preliminary results an order of magnitude increase in yield might be possible in the foreseeable future.

There are several other rather obvious conclusions which can be drawn from these results. The observed increase in yield with both decreasing discharge power intensity and residence time, whether an absorbing film is used or not, shows almost conclusively that hydrazine is being degraded by the discharge after its formation. This confirms the working basis for these methods of increasing hydrazine yields. Second, the observed fall in conversion with decreasing intensity of discharge power and residence time implies that the methods used to reduce the residence time of the product in the discharge are not entirely physical, and appear to affect the reaction mechanism. Finally, the yield from the pulsed discharge reactor can never be greater than the equilibrium concentration set by the basic reaction mechanisms leading to hydrazine formation. This is not the case with the absorption technique where equilibrium is never reached because hydrazine is removed as it is formed. Therefore the conversion for the pulsed reactor is likely to be smaller than that obtained using the absorption technique.

## Oxidation of Ethylene over Palladium and Palladium-Gold Alloys

UNTIL recently, nearly all successful catalysts used for the partial heterogeneous oxidation of ethylene contained silver as the active component<sup>1</sup>. In 1962, however, Kemball and Patterson<sup>2</sup> reported that ethylene could be oxidized to acetic anhydride and acetic acid over evaporated palladium films, and several applications have since then appeared in the patent literature<sup>3</sup>. Kemball<sup>2</sup> suggested that the partial oxidation products (which amounted to only about 3 per cent of the total) were formed by a path parallel to that for the complete oxidation to carbon dioxide. Acetaldehyde was proposed as the intermediate in the partial oxidation reaction, but none was detected, presumably because of its rapid oxidation to acetic anhydride. The purpose of the present work was to isolate and identify the proposed intermediate, and to determine whether higher selectivities might be obtained under more favourable reaction conditions.

A differential reactor was used in which the reactants were circulated rapidly over the catalyst at temperatures where the conversion in each pass was less than 1 per cent. The products were removed continuously from the gas phase by a U-tube trap maintained at  $-135^{\circ}\text{C}$ . In a typical experiment, 2 g of palladium sponge (99.95 per cent palladium, less than 10 p.p.m. silver, less than 15 p.p.m. chlorine; surface area,  $0.2\text{ m}^2/\text{g}$ ) were reduced in hydrogen at  $500^{\circ}\text{C}$  and then evacuated for 17 h at this temperature. A standard reactant mixture, containing 43 torr of ethylene and 100 torr of oxygen, was admitted to the reaction system and the gases circulated until about 30 per cent of the ethylene had reacted. The initial rates were close to zero order with respect to ethylene (in the range 10–47 torr) and 0.7 order with respect to oxygen (in the range 25–260 torr). The partial oxidation products, which represented 30–40 per cent of the ethylene oxidized, included acetaldehyde, acetic anhydride and acetic acid. The products were analysed by gas-liquid chromatography and identified by comparison with authentic compounds.

Acetaldehyde was confirmed by the following additional tests: (a) it had the correct retention time on a second (different) gas-liquid chromatography column (where a small quantity of ethylene oxide was also identified); (b) a positive test was obtained with fuchsin aldehyde reagent; (c) its mass spectrum corresponded to that of acetaldehyde. Depending on reaction conditions, acetaldehyde represented 1–20 per cent of the partial oxidation products.

The selectivity (percentage partial oxidation) was almost independent of temperature. In one series of experiments, it increased from 33 per cent at  $109^{\circ}\text{C}$  to 38 per cent at  $78^{\circ}\text{C}$ . These values, which are within our experimental error, indicate that the apparent activation energies of the two parallel reaction paths, if they exist, differ by less than 2 kcal/mole.

Unexpectedly, the selectivity was influenced by changes in oxygen pressure, increasing from 25 per cent to 43 per cent as the pressure was increased from 25 to 259 torr. This result can be explained if complete oxidation involves ethylene adsorbed associatively on adjacent metal atoms, while partial oxidation occurs on single sites. Alternatively, adjacent vacant metal atoms may effect complete oxidation by making possible the dissociative chemisorption of ethylene. The selectivity was not affected by changes in ethylene pressure between 10 and 47 torr.

The idea that the concentration of active sites for complete oxidation might be diminished by adsorption of oxygen led us to look for other ways of increasing the selectivity. Because gold was not a catalyst for this reaction, it was reasoned that the concentration of dual sites would be diluted in a palladium-gold alloy. This should favour partial oxidation. A poorly alloyed sample containing 18 atom per cent palladium was prepared by

reducing the mixed chlorides (obtained by evaporating a solution to dryness). Several experiments with this catalyst yielded selectivities as high as 70 per cent. Experiments with homogeneous alloys (verified by X-ray), prepared by reducing the metal salts with hydrazine, indicated that the selectivity reached a maximum at about 20 atom per cent palladium. Analyses showed, however, that samples prepared by reducing the metal salts with sodium borohydride were severely contaminated with sodium and boron. Our experience in this connexion makes us suspect the validity of using alloy catalysts prepared in this way to investigate the effects of alloying on catalytic properties, because these impurities drastically reduced both the rate and selectivity of the oxidation reaction. It is hoped that work now in progress will make it possible to interpret these results.

Fig. 1. Effect of temperature on rate.

The initial rates were measured over palladium as a function of temperature over the range  $71$ – $102^{\circ}\text{C}$  using the standard mixture of reactants. The Arrhenius plot is shown in Fig. 1. From the slope of this line, an apparent activation energy of 20 kcal/mole was calculated, and the initial rate could be expressed as

$$[d(\text{C}_2\text{H}_4)/dt]_{t=0} = 10^{24.6 \pm 0.1} \exp\left[-\frac{20,000 \pm 2,000}{RT}\right]$$

molecules/sec/cm<sup>2</sup>

The activation energy was about 6 kcal/mole greater than that found by Kemball and Patterson<sup>2</sup> for evaporated films. This discrepancy is outside our experimental error and may be attributed to the differences in catalyst preparations and reaction conditions. In particular, the reaction was first order in ethylene at the lower pressures used by Kemball and Patterson.

## Versatile Constant Transmission Photochemical Reactor

THE ultra-violet irradiation of organic and organometallic compounds in the liquid phase is often complicated by the tendency for deposition of an opaque layer of polymeric materials and other reaction products on the cell walls. With the use of apparatus of conventional type this tendency can cause the observed rates of photochemical reactions to decrease rapidly with time, and thereby make it impossible to investigate some reactions beyond very low conversions of the starting materials. Accurate quantitative work on relative reaction rates and quantum yields becomes very difficult.

We now describe a photochemical reactor in which the transmission of the cell can be kept constant over long periods even under irradiation conditions where an inner transmitting surface would normally be rapidly occluded. This reactor is illustrated in Fig. 1 and has as its key feature an arrangement whereby the inner surface in contact with the photolysate is continuously rubbed by means of a mechanically rotated pad of fused silica fibre. Temperature control is achieved by the circulation of water through an outer jacket of fused silica and, if necessary, a thermostat device of conventional type. Various optical filter solutions can be used in place of water when it is desired to isolate a particular wavelength range. Under normal conditions of use, and with occasional reversal of the direction of rotation of the scrubber pad, the transmission of the cell remains effectively constant for periods of 20–40 h or even longer. Ordinary glass fibre has been used in place of silica fibre, but is slightly less durable. Any conventional external ultra-violet radiation source can be used, preferably with an aluminium reflector. We use up to three 500-W medium pressure Hanovia lamps for routine purposes. The design is an improved version of one previously reported from this laboratory<sup>1</sup>.

The following typical result illustrates the general utility. Irradiation of a solution of *cyclooctene* in benzene under nitrogen is known to produce a 1:1 adduct of structure (I)<sup>2</sup>. If the pad of fused silica fibre is not rotated,

(I)

the rate of formation of adduct (I) falls rapidly with time from the initial value (about 2 g/h with one 500-W medium pressure Hanovia lamp) and is virtually zero within about 9 h. Under similar conditions, but with operation of the scrubber as described above, the initial rate of formation of adduct (I) is readily maintained for over 24 h.

The constant-transmission principle of this reactor has an obvious extension to gas-phase investigations.

## Spin Polarization in Atoms and $\pi$ -Radicals

IN certain radicals, sometimes referred to as  $\sigma$ -radicals<sup>1,2</sup>, the contribution to the orbital of the unpaired electron from one or more of the atoms involved includes a relatively high atomic  $s$  character, and this is manifested as a large isotropic hyperfine coupling. It is customary to estimate the  $s$  character by dividing this isotropic coupling by a calculated value ( $A^0$ ) for a spin density of unity in the appropriate orbital<sup>3</sup>. For  $\pi$ -radicals the isotropic hyperfine coupling constants of which are a consequence of spin-polarization or configuration interaction, however, the value is generally related, not to the atomic value,  $A^0$ , but to the value ( $Q$ ) that would have been obtained had the spin density in the  $p$  orbital of the atom concerned been unity.

Two correlations are revealed if these  $Q$  values are divided by the appropriate  $A^0$  value. (We have suggested that this ratio be given the symbol  $U$ .) The first is that when this is done for atoms such as nitrogen (normalized to one electron), the result is close to 0.2 per cent. The second is that for molecules having three  $\sigma$ -bonds to the atom in question the result is close to 4 per cent, and for all radicals tested it is never less than about 2 per cent. Although results for particular atoms and molecules have been discussed in great detail and refinement, this remarkable lack of sensitivity of the  $U$  values to the nature of the nucleus and bonding does not seem to have been recognized. Even more striking is the very large difference between results for atoms and those for molecules. This suggests to us that the dominating factor for molecules is polarization of the  $\sigma$ -bonding electrons and to a less extent non-bonding valence electrons having  $p$ - $s$  hybrid character, rather than of the core  $s$ -electrons. Perhaps the significant difference is the fact that for the molecules, the effective electrons are greatly attenuated away from the nucleus concerned and that this magnifies any spin-imbalance at this nucleus.

Details of these results will be published elsewhere. Here we wish to draw attention to the considerable utility of  $U$  values for radicals especially when considering the possibility of minor deviations from planarity<sup>3</sup>.

Fig. 1. A, Stirrer guide designed to avoid contamination with Nujol lubricant (ref. 3); B, 'B 19' joints; C, 'B 14' joints; D, borosilicate glass; E, 'B 50' joint with 'Teflon' sleeve; F, fused silica cell; overall length 35 cm, outside diameter 8 cm, working capacity about 400 ml.; G, annular gap of 1 cm or more for filter solution/coolant; H, hollow perforated borosilicate glass cylinder with hooks for attachment of fused silica fibre (the relative length can be greater than that indicated); J, bearing of 'Teflon' reinforced with glass fibre.

Also the remarkable insensitivity of the results to major changes in nuclei and bonding must be accommodated by any overall theory of the phenomenon.

### Method for estimating the Molecular Weight of Linear Polyethylene

A METHOD for estimating the molecular weight of a long chain linear polyethylene filament is discussed. This method is based on the assumed chain configurations of the polymer before and after extrusion from a jet, and on the straightening of the chain of the filament in a load elongation experiment. This filament can be considered as partially oriented at extrusion (jet stretch). The degree of such orientation is largely related to the speed of extrusion and the speed of taking up the filament. A typical load-elongation curve of a high crystalline, linear polyethylene filament is shown in Fig. 1. "Necking" begins after a few per cent of elongation. The load is approximately a constant during necking. After the completion of necking the load increases with further extension until the filament breaks.

The high crystalline polymer is melted before extrusion and thus the chains are randomly coiled. Let  $N$  be the average number of the C—C bonds in the chain. Then the end to end distance of the randomly coiled chain, calculated from the principle of random flight<sup>1</sup>, is  $c(2N)^{1/2}$  where  $c$  is the C—C bond length. After extrusion the polymer molecules recrystallize (assuming that the ratio of amorphous part to crystalline part is very small) and the segments of a chain are straightened in the crystalline regions. Let  $n$  be the average number of the C—C bonds in a straight segment. The average length of the straight segment is  $n \cdot c \cdot \sin \theta$ , where  $2\theta$  is the C—C—C angle ( $2\theta = 112^\circ$ ).

We first assume that each chain passes through a crystalline region without chain folding. The end to end

distance of a chain in the filament (assuming random orientation for the crystallites) is then given by

$$n \cdot c \cdot \sin \theta \cdot (2N/n)^{1/2}$$

We may then define the per cent jet stretch  $e_j$  as

$$e_j = 100 \left[ \frac{nc \cdot \sin \theta \cdot (2N/n)^{1/2}}{c(2N)^{1/2}} - 1 \right] = 100 [n^{1/2} \sin \theta - 1] \quad (1)$$

At the completion of necking in a load-elongation experiment, a chain which passes through a number of crystalline regions in the filament is approximately straightened without intermolecular sliding. Let  $e_n$  be the per cent elongation at the completion of necking; we then have

$$e_n = 100 \left[ \frac{cN \sin \theta}{nc \cdot \sin \theta \cdot (2N/n)^{1/2}} - 1 \right] = 100 \left[ \left( \frac{N}{2n} \right)^{1/2} - 1 \right] \quad (2)$$

Eliminating  $n$  between equations (1) and (2) we obtain

$$e_j + e_n (1 + e_j/100) = 100 [(N/2)^{1/2} \sin \theta - 1] \quad (3)$$

Next we assume that the crystalline region is formed by chain folding. A single polymer chain in the filament can form a series of crystalline regions of random orientation. Let  $L$  be the average number of times of chain folding in a crystalline region. Assuming  $L < n$  we then have

$$e_j \approx 100 \left[ \frac{nc \cdot \sin \theta \cdot (2N/nL)^{1/2}}{c(2N)^{1/2}} - 1 \right] = 100 [(n/L)^{1/2} \sin \theta - 1] \quad (4)$$

and

$$e_n \approx 100 \left[ \frac{cN \sin \theta}{nc \cdot \sin \theta \cdot (2N/nL)^{1/2}} - 1 \right] = 100 [(NL/2n)^{1/2} - 1] \quad (5)$$

From equations (4) and (5), equation (3) is again obtained.

The equations can be used to calculate  $N$  from estimated values of  $e_j$  and  $e_n$ , or to calculate  $e_j$  and  $n$  (or the ratio  $n/L$ ) for a certain extrusion condition from known molecular weight of the polymer and estimated value of  $e_n$ . For the filament used to obtain Fig. 1, we estimate  $e_j \approx 300$  and  $e_n \approx 600$ . From equation (3) we obtain  $N \approx 2,300$ . The molecular weight of this sample is about 32,000.

Part of the work was carried out at the Research Laboratory, American Viscose Corporation, Marcus Hook, Pennsylvania.

## BIOCHEMISTRY

### Biochemical Evidence for a Distinct Type of Primary Gout

IN recent years several reports<sup>1-3</sup> have called attention to a disorder occurring in the paediatric age group which is characterized by marked over-production of uric acid. The clinical features include haematuria and uric acid stone disease, and often, but not always, mental retardation, neurological signs, and self-mutilation. Intravenous injection of glycine-<sup>14</sup>C into such patients results in a rapid incorporation<sup>1</sup> of isotope into urinary uric acid,

signifying the presence of a shunt pathway whereby precursor is incorporated into uric acid without previous incorporation into nucleic acid purines.

Adult patients with gout characterized by over-production of uric acid show a similar but less marked pattern of incorporation of glycine into uric acid<sup>4,5</sup>. Recently, it has been shown that in the adult type of gout the shunt pathway can be abolished by administration of the synthetic purines azathioprine ('Imuran')<sup>6</sup> and allopurinol ('Zyloprim')<sup>6</sup>.

This communication reports on uric acid dynamics in a case of juvenile gout, and the failure of azathioprine and allopurinol to suppress *de novo* purine biosynthesis. The patient was a 13 year old boy who had had recurrent uric acid stone disease and haematuria since the age of 3. Except for mild choreiform movements in the outstretched arms and hands, and an area of self-induced alopecia, he presented no neurological signs.

The size of the miscible pool of uric acid and its rate of turnover were determined after intravenous injection of uric acid-2-<sup>14</sup>C (ref. 5). The incorporation of intravenously administered glycine-1-<sup>14</sup>C was determined three times: first during a period without treatment, and subsequently during treatment with azathioprine (4 mg/kg body weight per day) and allopurinol (400 mg/day). Glycine-1-<sup>14</sup>C was injected 96 h after treatment with azathioprine had begun, and on the twelfth day of allopurinol treatment.

Table 1 summarizes the results of the investigations. The daily production of uric acid was markedly enhanced to 2,396 mg/day, which, when corrected for body weight, represents a value of 42.8 mg/kg body weight. The normal endogenous production of uric acid is about 10 mg/kg daily. In contrast to the situation in adult gout with over-production of uric acid, azathioprine did not reduce either the plasma uric acid level or the urinary excretion of uric acid. Allopurinol produced a dramatic reduction in both plasma and urinary uric acid, but simultaneously there was an increase in the precursors of uric acid so that the total excretion of urinary oxypurines remained constant.

Table 1. SUMMARY OF DATA ON URIC ACID METABOLISM IN A CASE OF JUVENILE GOUT DURING A CONTROL PERIOD AND DURING PERIODS OF TREATMENT WITH AZATHIOPRINE AND ALLOPURINOL

	Control study	Azathioprine study	Allopurinol study
Miscible pool of uric acid (mg)	2,695		
Turnover of uric acid (mg/day)	2,397		
Mean plasma uric acid (mg per cent)	12.45	13.06	5.15
Mean urinary uric acid (mg/day)	1,741	1,778	344
Mean urinary uric acid formed from precursors (mg/day)	123		1,787
Mean urinary hypoxanthine (mg/day)	65		780
Mean urinary xanthine (mg/day)	38		787
Cumulative recovery of glycine- <sup>14</sup> C in urinary uric acid, 7 days (per cent of dose)	1.350	1.370	0.238

The strikingly accentuated incorporation of glycine into urinary uric acid may be compared with a normal incorporation of 0.1 to 0.15 per cent of the injected dose after seven days. The concentration of carbon-14 in urinary uric acid during the three glycine incorporation investigations is shown in Fig. 1. Although the maximum isotope concentration occurred later when azathioprine and allopurinol were given than in the control investigation, the shunt pathway was not suppressed by these compounds, and the cumulative recovery of carbon-14 in uric acid and its precursors was remarkably similar in all three investigations. With allopurinol, the cumulative recovery of carbon-14 in urinary uric acid was decreased, but when this figure was corrected for the simultaneous increase in hypoxanthine and xanthine the incorporation of glycine-<sup>14</sup>C into all oxypurines was comparable with the control value.

There is growing evidence for the view that purine biosynthesis is controlled by feedback inhibition. Wyngaarden *et al.*<sup>7</sup> have shown that glutamine phosphoribosylpyrophosphate amidotransferase, the synthesizing

Fig. 1. Concentration of carbon-14 in urinary uric acid following intravenous injection of 100  $\mu$ c. of glycine-1-<sup>14</sup>C at zero time into a patient with primary juvenile gout, during a control period, and during treatment with azathioprine and allopurinol. The broken curve on the left depicts the normal glycine incorporation pattern.

enzyme that catalyses the first reaction in purine biosynthesis, has at least two separate regulatory sites, one for adenylyl and one for guanylyl ribonucleotides. The results of the investigations presented here indicate that there is a distinction between the metabolic pathways in juvenile and adult patients with over-production of uric acid. They imply that in juvenile gout glutamine phosphoribosylpyrophosphate amidotransferase is insensitive to its normal allosteric feedback inhibition; it is conceivable that this may be related to structural alterations in those sub-units of the enzyme concerned with the binding of normal inhibitors.

### Gel Filtration using a Column packed with Elastin Fibres

THE molecular architecture of elastin as it exists in the water-swollen fibre is ill understood, but to account for the insolubility, rubber-like elasticity and swelling properties of the wet protein fibre its structure is regarded as a crosslinked gel. Chemical studies have shown that the peptide chains are organized as a three-dimensional network, crosslinked at intervals by covalent bonds<sup>1,2</sup>, and it has become usual to assume that between these links the chains are hydrated and in intimate contact with the swelling water. Studies of the rubber-like stress-strain characteristics of the wet fibres<sup>3</sup> indicate that there is no crystallinity, and suggest that the chains between the

crosslinks adopt a randomly crumpled conformation due to unrestricted thermal motion. In view of the large amounts of amino-acid with non-polar side-chains in elastin<sup>4</sup> it seems possible that sites of hydrophobic interaction of considerable size may occur in the network. Such a "corpuseular" model of elastin structure has recently been proposed to account for the behaviour of elastin with enzymes and for the course of fibrogenesis<sup>5,6</sup>. The distribution of the swelling water in the gel would be expected to have a marked influence on the behaviour of solute molecules diffusing in the water spaces, and the purpose of the present work was to examine the behaviour of such solutes using a chromatographic method.

Porath and Flodin<sup>7</sup> and others have shown that columns packed with crosslinked dextran gels are capable of sharp separations with solute molecules of different size. The dextran gels used in chromatographic gel filtration experiments have water regains in the range 7.5–20 g water/g dry gel, while the water content of the elastin gel is much less, about 2 g water/g dry protein. The elastin gel is therefore far more closely structured, but similar separation should be expected if the size of the test solutes is below that of the water-filled channels available for diffusion. In our experiments sugars, polyglycols and alcohols were chosen as uncharged solutes of a size suitable for separation using a column packed with elastin fibres.

The elastin fibres were prepared from the ligamentum nuchae of cattle 18 months to 2 years old, by extraction with 0.1 normal sodium hydroxide at 98° C for 45 min according to the method of Lansing *et al.*<sup>8</sup>. After extraction the fibre preparation was washed repeatedly with hot water until microscopic examination showed that the short smooth rod-like fibres (mean diameter 6.5 $\mu$ , length 0.15–0.50 mm) were well separated and the preparation contained no clumps.

The elastin fibres were suspended in 1 per cent v/v acetic acid and equilibrated by stirring gently for 48 h with repeated changes of solvent. The column (height 47.5 cm; internal cross section 2.27 cm<sup>2</sup>; volume 110.3 cm<sup>3</sup>) was poured in sections, using a thick slurry, and nitrogen under a pressure of 40 cm of mercury was applied to ensure rapid filtration and tight packing. Before applying the solutes, a large volume of degassed 1 per cent acetic acid was run through the column. The column was operated at 25° C with a rate of flow of 7 ml/h (nitrogen pressure 20 cm of mercury) and the fractions collected by means of a drop counter. The volume of the fractions was checked gravimetrically.

Fig. 1 shows the chromatogram obtained on applying a mixture of sugars (2 mg) and alcohols (40 mg each) together with cytochrome *c* (2 mg) to mark the void volume of the column. The mixture was applied in 1 ml. of 1

Fig. 1. The separation of a mixture of sugars and alcohols using a column packed with elastin fibres.

Fig. 2. The distribution coefficient ( $K_D$ ) between the water spaces in the elastin gel and the external water for a number of sugars, glycols and alcohols. Values for  $K_D$  greater than unity indicate adsorption on internal surfaces in the gel.

per cent v/v acetic acid and the column eluted with the same solvent. Cytochrome *c* with a molecular weight of 12,270 is not retarded under these conditions and shows no separation from bovine serum albumin, which has a weight of about 70,000. The sugars were estimated by the anthrone method<sup>9</sup>, cytochrome *c* by measuring extinction at 408 m $\mu$ , and the glycols and alcohols by permanganate oxidation. The mixture of solutes chromatographed in this experiment was chosen to display well separated peaks.

Chromatograms of the type shown in Fig. 1 can be used to calculate the distribution coefficients of the solutes between stationary phases and the flowing solvent phase. In the present experiments the relation of Gelotte<sup>10</sup>

$$K_D = \frac{V_e - V_o}{V_i}$$

was used to calculate the distribution coefficient ( $K_D$ ) of the solute between the water spaces in the swollen fibre and the external water. In this equation  $V_e$  and  $V_o$  are the elution volume of the solute and the void volume of the column respectively.  $V_i$ , the volume of solvent internal to the gel phase, was calculated from the measured water regain of elastin fibres in 1 per cent acetic acid at 25° C (55.8 per cent w/w = 63.1 per cent v/v). For the column used,  $V_i = 45.8 \times 0.631 = 28.9$  cm<sup>3</sup> and (from the position of the cytochrome peak)  $V_o = 64.5$  cm<sup>3</sup>.

Fig. 2 shows the distribution coefficient ( $K_D$ ) for a number of sugars, glycols and alcohols plotted against the cube root of the molecular weight of the solute. It will be seen that the sugars and glycols together fall into a uniform series, the distribution coefficients decreasing from values close to unity to very low values as the molecular weight increases. The polyglycols of very high molecular weight are almost entirely excluded from the water spaces in the gel, but a large part of the water in these spaces is available for the diffusion of ethylene glycol and sugars of low molecular weight.

The alcohols, on the other hand, fall into an entirely different series in which the lowest member (methanol) has a value for  $K_D$  just less than unity and the apparent distribution coefficient for the higher members is greater than unity. Thus for secondary amyl alcohol the apparent concentration in the stationary water phase is roughly

twice that in the surrounding solvent, indicating very marked absorption on internal surfaces in the protein gel. As would be expected, the adsorption of the alcohols depends greatly on the structure around the hydrophilic hydroxyl radical and the adsorption behaviour of the normal, secondary and tertiary homologues can clearly be distinguished. In all three homologous series adsorption increases with increasing molecular weight and increasing hydrophobic character. This suggests that the alcohols, unlike sugars and glycols, tend to be adsorbed at hydrophobic centres in the peptide fabric of the protein gel.

The results as a whole show that the wet elastin fibre contains water spaces of a size sufficient to allow the penetration of uncharged solutes with molecular weights up to about 1,500, and that while sugars and glycols are not adsorbed on the peptide fabric, even the lower alcohols show marked adsorptive effects. This adsorption is apparently brought about by hydrophobic interactions, and it may be presumed that the hydrocarbon side-chains of the non-polar amino-acids offer sites for adsorption.

I thank Mr. H. F. Davis and Mr. A. H. Whiting for much help with the experimental work, and Dr. G. S. Adair for valuable criticism and advice.

## Release of Enzymes from the Liver

DIFFERENT lesions of an organ lead to distinct enzyme patterns in the serum. Our knowledge about the mechanisms affecting the release of cellular enzymes from damaged tissues, however, is poor.

We studied the release of cellular enzymes in isolated perfused rat liver. By isolating the organ we were able to avoid the influence of extrahepatic factors and the superposition of enzyme patterns from various tissues. The rat livers were perfused by the method of Miller<sup>1</sup> as modified by Schimassek<sup>2</sup>. The cell free perfusion medium (a solution of physiological saline containing 25 g bovine albumin, 5.2 mmoles glucose, 1.3 mmoles lactate, and 0.1 mmoles pyruvate/l.<sup>2</sup>) was saturated with oxygen ( $pO_2$ , 300–400 torr.). The pH was adjusted to 7.30 ( $\pm 0.02$ ) and shifted during perfusion to 7.14 ( $\pm 0.02$ ). The temperature of the perfusion medium immediately after it entered the portal vein was 37° C ( $\pm 0.2^\circ$  C) and the flow was 1–3 ml./g liver/min.

The omission of erythrocytes from the perfusion medium caused a definite hypoxic lesion of the liver cells with a reduced consumption of oxygen (the gas analysis was carried out according to refs. 3 and 4). Simultaneously, leakage of enzymes from the liver was increased by lysing erythrocytes into the perfusion medium with a hypotonic solution. Histological sections and electron microscopy of normal liver under these conditions revealed that it was only slightly altered after 4 h of perfusion<sup>5</sup>. On average the loss of soluble protein (measured according to ref. 6) from the liver was 30 per cent. Within the 4 h of perfusion a remarkable increase in enzyme activity occurred in the circulating medium.

Fig. 1. Enzyme activities in the perfusion medium. (Ten perfusions; mean values.)

Fig. 1 shows the rise in activity of seventeen cellular enzymes in the extracellular space (the assays were performed according to refs. 7 and 8). In this figure, allowance has been made for the alterations which the enzyme activities undergo after release from the cells. These alterations consist of increases as well as decreases in activity. They depend on the composition of the perfusion medium, the dilution in the extracellular space, the temperature, the time, and are specific for each enzyme investigated<sup>9,10</sup>.

The enzyme pattern in the circulation system, as demonstrated in Fig. 1, is split into three groups of enzymes, the activities of which differ from each other by about an order of magnitude. It is evident from an analysis of this enzyme pattern that the rates of release of most of the enzymes investigated follow their respective concentration gradients between the liver and the circulation system: enzymes with high activities in the liver cell<sup>11,12</sup> reach high concentrations in the extracellular space, while those with low activities in the cell do not.

It can be seen from the upper part of Fig. 2 that the rate of release of most of the enzymes is inversely proportional to their respective molecular weights: the higher the molecular weight, the lower the percentage of intracellular activity found in the perfusion medium. GLDH, GOT and MDH\*, however, do not follow this rule. This indicates that the intracellular distribution delays the release from the cells: GLDH is solely in the mitochondria of the rat liver cell, which also contains more than 70 per cent of the GOT and 40 per cent of the MDH (refs. 12 and

\* Abbreviations: ADH, alcohol dehydrogenase; ALD, fructose-1,6-diphosphate aldolase; C, cytoplasmic; ENO, enolase; GAPDH, glyceraldehyde phosphate dehydrogenase; GDH,  $\alpha$ -glycerophosphate dehydrogenase; GLDH, glutamate dehydrogenase; GOT, glutamic oxalacetic transaminase; G-6-PDH, glucose-6-phosphate dehydrogenase (ZF); GPT, glutamic pyruvic transaminase; ICDH, isocitric dehydrogenase; LDH, lactic dehydrogenase; M, mitochondrial; MDH, malic dehydrogenase; PFA, fructose-1-phosphate aldolase; PGDH, 6-phosphogluconic dehydrogenase; PK, phosphoglycerate kinase; PK, pyruvate kinase; and SDH, sorbitol dehydrogenase.

Fig. 2. Rates of release of enzyme activities into the perfusion medium after 4 h perfusion plotted against the molecular weights of enzyme proteins. (Ten perfusions; mean values.)

13). The other enzymes investigated originate from the cytoplasm of the cells. Most of the activities of MDH and GOT found in the perfusion medium are derived from their cytoplasmic isoenzymes, as has already been shown by column chromatography<sup>5</sup>.

In the lower part of Fig. 2 it can be seen that these cytoplasmic isoenzymes behave like the other cytoplasmic enzymes, depending on their concentration gradient and their molecular weight. The concentrations of the mitochondrial isoenzymes, and the G6PDH, however, do not show this correlation. Unfortunately, as yet we cannot be certain of the molecular weights of mitochondrial GOT and MDH.

### Dependence of Uptake of Succinate by Mitochondria on Energy and its Relation to Potassium Retention

A LONG standing problem in mitochondrial metabolism is the origin of the inhibition of oxidation of anionic substrates which sets in on adding an excess of any agent which uncouples oxidative phosphorylation. It has been

noted that the inhibition is moved to higher uncoupler concentrations when the substrate concentration is raised<sup>1</sup>. This suggests that for some reason the permeation of substrate fails to keep up with the metabolic demand in presence of excess uncoupler. This supposition accords with observations that the respiratory carriers are left in an oxidized condition when inhibition supervenes<sup>2</sup>.

Parallel studies of the metabolic effects of agents which induce ion permeability, such as valinomycin, led to the finding that the maximal respiration attainable on adding an uncoupling agent could be increased by prior induction of a high permeability to potassium ions, with its attendant uptake of potassium, particularly at low substrate concentration (for example, 3 mmolar). Furthermore, the maximal rate of respiration attainable is consistently higher in a 150 mmolar potassium chloride medium than in a sucrose medium free of potassium ions. Release of potassium ions, when caused by addition of nigericin, has been shown to lead to inhibition of metabolism<sup>3</sup>.

Taken together, these facts suggested that the retention of potassium ions or the direction of the net movement of the ions is related to the ease of entry of certain substrate anions and thus to the maximal respiratory capability. We sought to test this; Fig. 1 shows records taken simultaneously of respiration, light scattering and the concentration of potassium ions in the medium during successive additions of valinomycin and the uncoupling agent trifluoromethoxycarbonylcyanidephenylhydrazide<sup>4</sup>. The valinomycin causes movement of potassium ions from the medium into the mitochondria and a swelling, shown by reduction of light scattering signal. A small dose of FCCP stops the uptake of potassium ions and induces a high respiratory rate while a further dose of FCCP leads to respiratory inhibition after a slight delay. The records show that potassium ions are lost from the particles, which shrink. A similar end result is obtained without the prior addition of valinomycin; respiratory inhibition sets in soon after loss of the endogenous potassium has started.

Measurements of the uptake by mitochondria of substrates labelled with carbon-14 have been made by the centrifugal method described previously<sup>5,6</sup>. Table 1 shows mean values of duplicate experiments run in parallel and allows comparison of the amounts of succinate plus metabolic products (fumarate and malate) in the mitochondria after brief (10 sec) incubations in media with or without additions of substances known to alter either energy production or potassium retention. Agents which uncouple oxidative phosphorylation when applied at levels sufficient to inhibit respiration (as found in other experiments) caused a marked diminution of uptake of labelled succinate (compare lines 2, 3 and 4 with line 1).

Fig. 1. Simultaneous recordings<sup>4</sup> of light scattering (L.S.), oxygen concentration ( $O_2$ ) and potassium concentration (K) were made from a suspension of rat liver mitochondria (2 mg/ml), in a medium containing: 250 mmolar sucrose; 20 mmolar tris chloride pH 7.4; 2 mmolar potassium chloride; 3 mmolar tris-glutamate; 3 mmolar tris malate. Further additions of valinomycin (Val) and trifluoromethoxycarbonylcyanidephenylhydrazide (FCCP) were made as indicated. Swelling is indicated by a downward deflexion of the light scattering trace.

Table 1

Addition	Experiment 1	Experiment 2	Experiment 3	Experiment 4
1. —	2.4	3.4	2.2	1.8
2. 10 $\mu$ molar TTFB	0.8	—	—	—
3. 200 $\mu$ molar dicumarol	—	1.2	—	1.2
4. 3 $\mu$ molar FCCP	—	—	1.6	—
5. 0.2 $\mu$ g/g valinomycin	—	—	3.4	—
6. 0.3 $\mu$ g/g nigericin	—	—	1.2	—
7. 0.6 $\mu$ g/g antimycin A	—	—	—	1.9
8. 0.25 $\mu$ g/g oligomycin + 0.25 $\mu$ g/g antimycin A	—	—	—	0.8

Concentration ratios of succinate- $^{14}$ C between total water of rat liver mitochondria and medium after approximately 10 sec exposure time at 22° C. Reaction was carried out by centrifugation of the mitochondria through a medium containing a 1 mmolar succinate- $^{14}$ C (3 mmolar in experiment 3), 250 mmolar sucrose, 20 mmolar *tris* chloride pH 7.4, and 5 mmolar potassium chloride and 0.5  $\mu$ g/ml. rotenone, collecting the mitochondria in acid and by measuring the amount of succinate- $^{14}$ C taken up with a liquid scintillation counter.

There was no effect on uptake if these agents were applied at levels at which respiration was stimulated. In experiments like that illustrated in Fig. 1 the high level of uncoupling agent leads to potassium discharge; a discharge of potassium ions is also induced by nigericin and it too inhibits substrate entry (line 6). On the other hand, addition of valinomycin, which promotes potassium uptake (as seen in the first part of Fig. 1), stimulates uptake of the succinate (line 5). The addition of antimycin, which inhibits respiration, failed to decrease the uptake of succinate (line 7); this result is important for two reasons: (1) it shows that succinate itself can be accumulated because the material labelled with carbon-14 will not be oxidized; and (2) it shows that the endogenous adenosine triphosphate (ATP) can provide energy for substrate transport in the absence of respiration. The latter point is confirmed by the very small entry (line 8) obtained when oligomycin is used to block the utilization of ATP in presence of antimycin which has been used to block respiration.

Unambiguous examples of accumulation of an anion in conditions in which it is not oxidized have also been obtained using labelled acetate or citrate in the presence of rotenone, with succinate as energy source.

Because the data obtained to date do not allow us to decide in which part of the mitochondrion the anions are accumulated, the concentration ratios given in Table 1 are computed for the total mitochondrial water. The actual gradient of concentration may be much greater, however, if the substrate is accumulated in the sucrose impermeable space which comprises only approximately one-third of the mitochondrial water. Conditions which give rise to potassium loss are associated with reduced uptake of substrate, while stimulated potassium uptake is accompanied by an increase in substrate uptake. This agrees with the conclusion of Lynn and Brown<sup>7</sup>. It is difficult to decide at present whether there is a common energy dependence of the two parallel processes or whether active uptake of one ionic species is a prerequisite for movement of the other species.

## Acetate Repression of Chlorophyll Synthesis in *Euglena gracilis*

THE photosynthetic apparatus of *Euglena gracilis* is exceptionally labile and can be bleached by a variety of chemical and physical agents. During a recent series of experiments on streptomycin<sup>1</sup>, heat<sup>2</sup> and hydroxyurea<sup>3</sup> inhibition of chlorophyll synthesis in *Euglena*, it was noted that cells grown in the presence of excess sodium acetate contained less chlorophyll than cells grown with smaller amounts of acetate. This observation led to the present experiments.

Stock cultures of *Euglena gracilis*, strain Z, were grown at room temperature in a medium containing the following per litre: 2.5 g proteose-peptone, 2.5 g bactotryptone, 0.1 g yeast extract, 0.1 g  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$  and 1 g each of glucose, potassium dihydrogen phosphate, potassium monohydrogen phosphate and sodium acetate. Subsequent greening experiments with various amounts of acetate were carried out at room temperature with incandescent light (100 W) placed above the culture flasks. Cell counts were made with a microscope with a Whipple disk and Sedgwick-Rafter counting chamber. Cells were concentrated by centrifugation and chlorophyll was extracted with 80 per cent acetone for 2 h in the dark. The optical density of the extract was measured at 663 and 645 m $\mu$ . Chlorophyll concentration was calculated according to Arnon<sup>4</sup>.

Fig. 1 shows the effect on growth and chlorophyll synthesis of *Euglena* of raising the concentration of acetate from 11.5 mmoles/l., the usual amount, to 112 mmoles/l. Both growth and chlorophyll synthesis were inhibited, the latter being the more sensitive. By 120 h, chlorophyll content per millilitre of the high acetate culture was only 15 per cent of that found in the low acetate culture.

Fig. 1. Growth and chlorophyll synthesis of *E. gracilis* in the presence of low (Δ) and high acetate (○). Initial chlorophyll/ml. was 0.15  $\mu$ g and initial cell number/ml. was 7,200.

Furthermore, no increase in chlorophyll/ml. was observed in the high acetate culture after 96 h. Thus, because the number of cells in this culture increased between 96 and 120 h, the amount of chlorophyll present actually decreased from 7.7  $\mu\text{g}/\text{cell}$  at 96 h to 4.9  $\mu\text{g}/\text{cell}$  at 120 h. Low acetate cells contained 16.6  $\mu\text{g}$  chlorophyll/cell at 120 h. On the basis of these results, it was decided to run a series of acetate concentrations together with an added control culture lacking acetate. Table 1 shows that the culture lacking acetate synthesized the most chlorophyll per cell in 96 h. Cultures were initially inoculated with 9,000 cells/ml. and all cultures were in the late log phase or early stationary phase of growth at this time. The usual growth condition (11.5 mmolar acetate) was inhibited 33 per cent. Inhibition of chlorophyll synthesis reached 73 per cent with 45.7 mmolar acetate, but the inhibition did not increase with higher concentrations of acetate. It was further observed that cells grown in 23 mmolar or higher concentrations of acetate were densely packed with paramylon granules, the carbohydrate storage product of *Euglena*. This observation agrees with that of Pringsheim and Pringsheim<sup>5</sup>, who noted an increased content of paramylon granules in *E. gracilis* grown with 14.7 mmoles/l. or more acetate. The inhibition of the synthesis of chlorophyll, however, imposed by 112 mmolar acetate, for example, was readily reversed. Under sterile conditions, 10 ml. of cells from the 96 h culture (Table 1) was concentrated by centrifugation at 4° C, washed once with 0.9 per cent sodium chloride, resuspended in normal medium (11.5 mmolar acetate) and placed within 16 in. of the 100 W light. By 48 h the chlorophyll content/10<sup>7</sup> cells was 154  $\mu\text{g}$ , and by 74 h it was 181  $\mu\text{g}$ .

Table 1. INFLUENCE OF ACETATE ON CHLOROPHYLL CONTENT OF *E. gracilis*

Acetate (mmoles/l.)	Chlorophyll ( $\mu\text{g}/10^7$ cells)
0	181
11.5	123
23.0	85
45.7	49
90.0	44
112.0	49

Cultures were grown for 96 h at room temperature and then sampled for chlorophyll determination.

The early observation of Hall<sup>6</sup> showed that the growth of *E. stellata* on complex medium was somewhat inhibited at concentrations of acetate greater than about 24.4 mmoles/l. Ternetz<sup>7</sup> even earlier had noted a fading of the green colour of *E. gracilis* var. *bacillaris* when it was inoculated into a rich organic medium. App and Jagendorf<sup>8</sup> showed that non-multiplying *Euglena* incubated in phosphate buffer with 8.1 mmolar acetate contained only 38 per cent and 77 per cent as much chlorophyll as control cells in buffer alone at 18 and 36 h respectively. The present investigation further shows that excess acetate not only represses the synthesis of chlorophyll in multiplying *Euglena*, but also leads to a concomitant increased synthesis of paramylon. Such an effect presumably has adaptive significance because ultimately the cells must use storage material for the synthesis of chloroplasts and basal metabolism when external acetate is used up. Support for this interpretation is found in the recent work of Cook<sup>9</sup> which shows that carbon fixed in photosynthesis in *Euglena* is routed almost exclusively into protein when acetate is present, whereas the acetate incorporated mainly enters lipid and polysaccharide.

Magasanik<sup>10</sup> showed that, in addition to glucose, any carbon compound efficiently used as a source of intermediary metabolites and of energy by a micro-organism can repress certain inducible enzymes. Unlike the effect of excess glucose on *Chlorella*<sup>11</sup>, the repression of chlorophyll synthesis in *Euglena* by acetate is not complete. Increasing amounts of acetate increasingly inhibit chlorophyll synthesis, but a maximum inhibition of about 75 per cent occurs when the concentration of acetate is 45.7 mmoles/l. and greater (Table 1). It would seem that

in *Euglena* acetate can strongly repress certain enzymes used during the final maturation of the chloroplast. The present investigation, however, indicates the existence of cellular control mechanisms which prevent total repression by acetate of chlorophyll synthesis in *Euglena*.

### Isoamylases of Human Parotid Saliva

COLUMN electrophoresis with a polyacrylamide gel was used by Muus and Vneuchak<sup>1</sup> to separate from crystalline human saliva amylase four protein staining bands which suggested four different molecular forms of amylase. The staining evidence was corroborated with the finding of four areas of amylase activity from gel section eluates. A more direct method with greater resolving power for detecting the multiple molecular forms of amylase has been developed for use with polyacrylamide gel columns. Preliminary studies show that there are generic differences in salivary amylase and that a polymorphism exists among human parotid salivas.

Parotid saliva was bilaterally collected from selected individuals by using modified Carlson and Crittenden cups. The salivary flow was stimulated by having the patient taste *ad libitum* a commercial, natural strength, reconstituted lemon juice<sup>2</sup>. Whenever practicable, electrophoresis was performed on the day of collection; otherwise, the samples were lyophilized and stored in a freezer. These samples were reconstituted in the electrophoresis buffer just before use.

Crystalline preparations of both the pooled and individual saliva samples were made by the method of Fischer and Stein<sup>3</sup>. Electrophoretically purified salivary amylase was prepared by paper electrophoresis, removing the amylase section and recovering the amylase by eluting in water and lyophilizing. The Durrum type electrophoresis cell was used with veronal buffer, pH 8.6, ionic strength of 0.05, 8 pre-cut S and S 2043 A mgl strips per run for 23 h at 200 V of constant voltage. For a comparative study rat parotid saliva was collected by the method of Wolf, Kakehashi, and Taylor<sup>4</sup>.

Fifteen  $\mu\text{l}$  of parotid fluid were subjected to electrophoresis at 10 m.amp per gel for 60 min at 2°–5° C on a polyacrylamide gel column by the method of Ornstein and Davis<sup>5</sup>. Following electrophoresis the acrylamide gel column was placed on a starch-agar coated glass slide. 2 ml. of the following mixture had been previously pipetted on to a microscope slide and allowed to dry at room temperature: 1 g noble agar, 0.25 g starch (hydrolysed), 0.25 g amylopectin and 10 ml. of 0.1 M, pH 6.9, phosphate buffer also containing 0.1 M sodium chloride diluted to 100 ml. The column was then compressed to about 3 mm by another glass slide and incubated for 15 min at room temperature. Amylase position was indicated by clear zones on a purple field of starch iodine complex after the incubated starch-agar gel slide had been developed in an iodine-potassium iodine solution (0.01 M iodine and 0.01 M potassium iodine) for 15 sec.

The zymogram patterns of Fig. 1 illustrate the effect of preparation and sampling. Seven bands are seen in Fig. 1a, and five bands are seen in Fig. 1b. The seven bands of the zymogram Fig. 1a were obtained when testing amylase crystals from a pooled human parotid saliva sample. The five bands of Fig. 1b were obtained when amylase crystals from the parotid saliva of one person were subjected to electrophoresis. The finding of more bands with the pooled sample crystals than with the crystals from a single source indicated that the pooled sample had components which the non-pooled sample did not. This finding was taken to indicate the existence of a polymorphism and corroborating evidence will be given later in this paper. Using a comparable method of separation but testing a crystalline pooled whole human saliva sample and using a different detection method, Muus found four areas of amylase activity. She also speculated that there may be "... differences among the amylases secreted by different individuals"<sup>1</sup>. We found variation in the intensity of the bands and this feature may prove to be a distinguishing characteristic as has been found with LDH (ref. 6) and animal amylase studies<sup>7-9</sup>. Trailing was found to be negligible because the weaker bands migrate farther and the strongest was usually next to the slowest band.

The parotid saliva amylase zymograms of Fig. 1a, b and c were products of samples collected at different times and prepared by different methods. Those samples receiving less preparative treatment appeared to be similar. The effect of sampling time variation was negligible because repeated samples from individuals yielded identical amylase zymograms. After the more drastic treatment of crystallization, the zymogram Fig. 1b (5 bands) showed less resemblance to the zymogram of Fig. 1d (7 bands) which was produced from an untreated parotid saliva sample. The sample which was purified by paper electrophoresis, Fig. 1c, and the untreated parotid saliva sample, Fig. 1d, yielded zymograms with seven bands similar both in relative density and banding order. A greater difference was found between the crystallized sample and untreated

Fig. 1. Zymograms of human parotid salivary isoamylase illustrating variation by preparation. Electrophoresis was on 7.5 per cent polyacrylamide gel for 1 h at 4 ma/gel. The buffer was a 0.025 M tris (hydroxymethyl) aminomethane and 0.192 M glycine of pH 8.3. The spacer gel was at the top of the gel columns (left side of illustration) and migration toward the anode. (a) From amylase crystals of pooled parotid saliva (8 individuals). (b) From amylase crystals of one person; one of the authors (R.O.W.). (c) From paper electrophoretically purified amylase of parotid saliva from R.O.W. (d) From neat parotid saliva of R.O.W.

Fig. 2. Zymograms illustrating parotid saliva amylase species differences. (a) Rat parotid saliva. (b) Human and rat parotid saliva. (c) Human parotid saliva.

sample than was found between the sample purified by paper electrophoresis and the untreated sample. This illustrates the effect of treatment. Muus<sup>1</sup> as well as Kaplan<sup>10</sup> recognized the possibility of purification procedures introducing artefacts by changing the properties of isoenzymes.

The zymogram of the electrophoretically purified amylase (Fig. 1c) illustrates the resolving power of the polyacrylamide gel column electrophoresis compared with that of paper strip electrophoresis. Where the one amylase band was recovered from paper electrophoresis and then subjected to electrophoresis on the acrylamide gel system, seven bands were detected. It was concluded that the isoenzymes of amylase are separated as one band during paper electrophoresis at pH 8.6.

The results of mixing parotid saliva of human and rat are shown in Fig. 2. The amylases of these two species are different with respect to the rate of electrophoretic migration and they maintain a high degree of autonomy when mixed, suggesting amylase differences among genera.

Table 1. NUMBER OF PAROTID SALIVA ISOAMYLASE BANDS FOUND IN ELEVEN INDIVIDUALS

No. of bands	Individual frequency
5	3
6	6
7	1
8	1

By using the same quantity of saliva for each electrophoresis we have found that a polymorphism exists among the population tested. The number of parotid saliva isoamylase bands found in eleven individuals is given in Table 1.

### Radioimmunoassay of Bradykinin

In the past few years highly sensitive and specific radioimmunoassay methods have been developed for the determination of many polypeptide hormones<sup>1</sup>. Radioimmunoassays are usually based on the competitive reaction of a measured amount of polypeptide hormone labelled with iodine-125 and iodine-131 and varying amounts of unlabelled hormone with hormone antiserum. This report describes a radioimmunoassay technique for bradykinin, a nonapeptide of considerable physiological and pathological importance. Bradykinin differs from other polypeptide hormones, which have been assayed by this method, in its lack of immunogenicity and inaccessibility to iodination. Formation of antibody against this peptide was therefore induced by immunizing goats with a bradykinin-haemocyanin conjugate<sup>2</sup>. An isotopic label was introduced into the molecule by acetylating its terminal amino-group with <sup>14</sup>C-acetic anhydride<sup>3</sup>. This approach makes it possible to use commercially available bradykinin and renders an isotopic synthesis of the peptide unnecessary. Antibody which binds <sup>14</sup>C-acetyl bradykinin was demonstrated in antiserum by a gel filtration procedure which separates antibody-bound from unbound peptide. Partial to complete displacement of the labelled acetyl peptide from its antibody-complex was observed on addition of increasing amounts of unlabelled bradykinin or acetyl bradykinin to the incubation mixture of a fixed amount of <sup>14</sup>C-acetyl bradykinin and antiserum. Unlabelled bradykinin was found to be about 10–20 times less effective in this reaction than unlabelled acetyl bradykinin.

Haemocyanin of molecular weight  $7 \times 10^6$ , apparently homogeneous by sedimentation velocity and electron microscopy, was isolated from keyhole limpets and kept at  $-20^\circ\text{C}$  until used. The conjugate was prepared as follows: 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide (825 mg) was dissolved in 2 ml. of saline and added dropwise with stirring to a solution of 55 mg of haemocyanin and 100 mg of bradykinin triacetate in 3 ml. of saline. The mixture deposited a gelatinous precipitate and was allowed to stand at room temperature for 30 min. It was then dialysed against two changes of 2,000 ml. saline for 60 h in the cold room. Amino-acid analysis of a hydrolysed sample indicated that approximately 15  $\mu\text{moles}$  of bradykinin had been incorporated in each 100  $\mu\text{g}$  of haemocyanin. Two goats were immunized by subcutaneous and intramuscular injection of the conjugate suspended in Freund's complete adjuvant. Each goat received 100 mg of the conjugate over a period of 3 months. The animals were bled 3 weeks after the last injection and were then given further immunizations over a period of 6 months with periodic bleedings. Pre- and post-immunization sera were stored at  $-20^\circ\text{C}$  for immunoassay.

Bradykinin triacetate was dissolved in a minimum of acetic acid and allowed to react with a 20 molar excess of acetic-<sup>14</sup>C-anhydride at room temperature for 3 days. Excess acetic acid and anhydride was removed *in vacuo*. The O-acetyl group (serine) was hydrolysed by treatment of the residue with 0.1 molar *tris* buffer at pH 8.7. After acidification and removal of acetic acid and solvent *in vacuo* the product was purified by ion-exchange on an 'Amberlite CG-50' column<sup>5</sup>. The purified <sup>14</sup>C-acetyl bradykinin was checked by paper chromatography against a sample of unlabelled acetyl bradykinin. Both samples had  $R_F$  values of 0.42 (*n*-butanol-acetic acid-water 90:10:25) and gave a positive Sakaguchi stain but a negative ninhydrin reaction. All radioactivity was located in the area of the Sakaguchi stain. <sup>14</sup>C-acetyl bradykinin was found to possess half the biological activity of bradykinin in the rat uterus assay<sup>6</sup>. Pre-immunization serum or antiserum (1 ml.) was incubated for 30 min at  $5^\circ\text{C}$  with a fixed amount (0.36  $\mu\text{g}$ ) of <sup>14</sup>C-acetyl bradykinin in 0.5

ml. of borate buffer (0.01 molar, pH 7.5) made up in 0.9 per cent saline. The buffer also contained bacitracin (0.5 mg/ml.) or lysozyme (1 mg/ml.) to prevent adsorption of the peptide to glass, and arginine (0.46 mg/ml.), an inhibitor of bradykininase<sup>7</sup>. The concentration of peptide present in the test solutions was checked by amino-acid analysis of hydrolysed samples. Incubation mixtures were applied to a  $0.9 \times 40$  cm column of 'Sephadex G-50' and developed with the borate buffer at  $5^\circ\text{C}$ . The effluent was collected in 1 ml. fractions and its radioactivity determined in a scintillation counter<sup>8</sup>. Binding of <sup>14</sup>C-acetyl bradykinin by antiserum was demonstrated by the emergence of radioactivity in the void volume (peak 1, Fig. 1). The percentage of labelled hapten bound by antibody is represented by A in the first peak and unbound radioactive hapten by A in the second peak. When varying quantities of unlabelled peptides (B, 0.33  $\mu\text{g}$  unlabelled acetyl bradykinin; C, 5  $\mu\text{g}$  unlabelled bradykinin; and D, 20  $\mu\text{g}$  unlabelled bradykinin) were added to the incubation mixture, corresponding decreases of radioactivity in peak 1 and increases in peak 2 were observed, indicating partial to complete displacement of labelled acetyl bradykinin by unlabelled peptides. When pre-immunization control serum was used all radioactivity was found in peak 2.

The unexpected finding that antiserum binds acetyl bradykinin much more strongly than unacetylated bradykinin (Fig. 1) may be explained by the fact that at least part of the antibody formed is directed against a conjugate in which bradykinin is acylated by carboxyl groups of haemocyanin. Such a derivative is chemically and immunologically more closely related to acetyl bradykinin than the unacetylated peptide.

The sensitivity of this assay can be increased greatly by using tritiated acetyl bradykinin of higher specific activity (<sup>3</sup>H-acetic anhydride, 3,000 mc./mmole, available from Nuclear Chicago Corp.). This would permit detection of less than 0.005  $\mu\text{g}$  of bradykinin and suffice for the determination of blood levels in patients with carcinoid syndrome. Concentrations of 0.39–1.2  $\mu\text{g}$  bradykinin/ml. have recently been reported in this condition<sup>9</sup>. For the assay of much smaller quantities in greatly reduced volumes of blood a bradykinin derivative of still higher specific activity might be prepared by acylation with an group such as pipsyl bearing iodine-125 or iodine-131. Work to this end is progressing in our laboratories.

As this paper was being submitted for publication an article appeared which describes a similar radioimmunoassay<sup>10</sup>. Antibody against bradykinin was obtained by immunization with a polylysine-bradykinin co-polymer and labelled hapten was produced by acetylation with tritiated acetic anhydride.

Fig. 1. A constant system of antiserum (1 ml.) and <sup>14</sup>C-acetyl bradykinin (0.36  $\mu\text{g}$ ) was incubated with: A, no addition; B, 0.33  $\mu\text{g}$  unlabelled acetyl bradykinin; C, 5  $\mu\text{g}$  unlabelled bradykinin; D, 20  $\mu\text{g}$  unlabelled bradykinin; d.p.m., disintegrations per minute. Bars of peak 1 represent pooled eluate collected in tubes 11–15 of individual experiments; peak 2, pooled eluate collected in tubes 23–30.

\* While this work was in progress two reports appeared in the literature describing similar approaches in the development of radioimmunoassays for angiotensin and growth hormone<sup>11,12</sup>.

We thank Dr. J. M. Stewart for a gift of unlabelled acetyl bradykinin.

This work was supported by grants from the U.S. Public Health Service.

### Membrane Filtration for determining Protein in the Presence of Interfering Substances

SEVERAL substances that are present in biological materials and some compounds which are added during protein purification procedures interfere with protein determinations by the biuret and Folin-phenol procedures<sup>1</sup>. For example, substances with two or more peptide bonds and ammonium salts give a positive biuret reaction and aromatic amino-acids, uric acid, guanine, and xanthine cause similar difficulties in the Folin-phenol method. Reducing agents such as 2-mercaptoethanol interfere with both procedures. The effects of these substances can be minimized if protein samples are analysed after being precipitated, centrifuged and further washed with trichloroacetic acid (TCA). If, however, the initial protein solution is very dilute and large portions must be taken for analysis, or if only a small amount of protein is to be assayed, problems arise in recovering and washing the precipitated protein free of interfering substances. Micromethods have been devised<sup>2</sup> to surmount these problems, but for routine analysis a rapid and effective procedure is needed for removing these undesir-

Fig. 1. Biuret determination of bovine serum albumin by a standard procedure (○) and by the membrane filter method after precipitation with trichloroacetic acid (●).

Fig. 2. Folin-phenol procedure for determination of bovine serum albumin by a standard procedure (○) and by the membrane filter method after precipitation with trichloroacetic acid (●).

able substances and determining protein. These requirements appear to be fulfilled in the method reported here. This method involves the analysis of protein precipitated by TCA and then separated from interfering substances by membrane filtration on 'Millipore' filters.

Both the biuret<sup>3</sup> and Folin-phenol<sup>2</sup> reagent procedures have been adapted for the membrane filtration method. In the biuret and also in the Folin-phenol procedure, the protein is precipitated with TCA (5–7 per cent final concentration), collected on a 'Millipore' filter and washed with 5–10 ml. of TCA. Filters (25 mm diameter) with pore diameter of 0.45, 3.0, 5.0 and 8.0  $\mu$  were equally effective. While the filter is still in position on the filter holder, it is cut into quarters with a razor blade and the sections transferred to a 1.5  $\times$  10 cm test-tube.

In the biuret method, 0.1 ml. sodium hydroxide (0.1 normal) is added to the protein filter sample and the mixture vibrated or "buzzed", then allowed to remain at room temperature for 15 min, with occasional "buzzing". Prolonged exposure to sodium hydroxide and a higher concentration of sodium hydroxide should be avoided because the filters will dissolve and liberate phenolic substances that interfere with the protein determination. 0.4 ml. of water is then added and the reaction mixture "buzzed". Biuret reagent<sup>3</sup> (2 ml.) is added with "buzzing" and the mixture is then allowed to stand for 30 min at room temperature. The optical density (Klett units) at 540 m $\mu$  is determined against a blank consisting of a 'Millipore' filter carried through the entire procedure. In Fig. 1 representative data for this method are compared with data for a bovine serum albumin standard that was not precipitated.

For the Folin-phenol procedure, 0.5 ml. of 0.1 normal sodium hydroxide is added to the protein-filter sample, the mixture "buzzed" several times during a 15 min period, and then 0.5 ml. of water is added with mixing. 5.0 ml. of reagent D (ref. 2) (carbonate-copper solution) are added to the sample, mixed, and after 15 min 0.5 ml. of reagent E (Folin-phenol reagent)<sup>2</sup> is added. The mixture is "buzzed" and the optical density at 660 m $\mu$  is determined after an additional 30 min. A 'Millipore' filter carried through the entire procedure is used as a blank. Fig. 2 compares the determination of protein by the filter method with non-precipitated standards.

As shown in Table 1, high concentrations of several interfering agents did not affect protein determinations when the membrane filtration method was used. It is essential, however, that this type of information be

Table 1. EFFECT OF INTERFERING SUBSTANCES ON PROTEIN DETERMINATION BY THE MEMBRANE FILTRATION TECHNIQUE

Interfering substance added	Klett units	
	Biuret reagent	Folin-phenol reagent
None	59	52
Ammonium sulphate, 450 mmolar	56	49
2-Mercaptoethanol, 45 mmolar	55	48
Glutathione, 45 mmolar	55	56
Tyrosine, 4.5 mmolar	61	50
Xanthine, 9.0 mmolar	58	—

Each protein sample contained the compound at the final concentration indicated in a total volume of 1.0 ml. 1.0 mg protein was used in the biuret assay; 0.05 mg in the Folin-phenol. Blanks, that is, no protein, were found, for each addition, to be identical to a standard 'Millipore' filter blank.

obtained for an interfering compound under consideration because some materials are adsorbed to membrane filters.

The optical densities of samples determined by the biuret-filter method (Fig. 1) were almost identical to standard protein determinations without precipitation. The values, however, obtained by the Folin-filter method (Fig. 2), for reasons not yet determined, were consistently lower than with protein standards that had not been precipitated. This fact makes it necessary to establish standard curves by precipitating known amounts of protein. Although the membrane filtration method is less sensitive for small amounts of protein, it is, nevertheless, as effective as standard methods over a wide range of protein content (40–2,000 µg). The important feature of the filter procedure is that it provides a rapid method for protein determinations on dilute solutions of protein containing substances which interfere with the standard biuret and Folin-phenol procedures.

I thank Miss Sharon Smith for technical assistance.

## Urinary Excretion Patterns of Individual Acid Mucopolysaccharides

DURING recent years several authors have shown that certain hereditary dysostoses are caused by an abnormal deposition in bone and various parenchymatous organs of acid mucopolysaccharides (AMP). Maroteaux and Lamy<sup>1</sup> subdivided these mucopolysaccharidoses into five different types according to their characteristic excretion patterns of AMP. In this communication we present our results of a comparable investigation of urinary excretion of individual AMP in normal persons and patients with different types of mucopolysaccharidoses. Through the introduction of column chromatography the determination of AMP pattern in the urine has become an especially valuable tool in the biochemical identification and classification of atypical cases of hereditary dysplasias of bone.

Acid mucopolysaccharides in the urine of eight normal individuals of both sexes and various ages, four patients with gargoylism (Pfaundler-Hurler) and one patient with polydystrophic oligophrenia (type Sanfilippo) were fractionated. The procedure included precipitation of urinary AMP material with cetyltrimethylammonium bromide and subsequent column chromatography on 'Dowex 1 X 2' (ref. 2). The hexuronic acid content of each fraction was determined by the carbazole reaction<sup>3</sup> and the anthrone reaction<sup>4</sup>, respectively. Details of the method used have been reported elsewhere<sup>5</sup>.

Normal persons of various ages have a typical excretion pattern of urinary AMP. In Table 1 the values are compiled of four AMP excreted by healthy individuals. The data are expressed in terms of percentages of the total carbazole material determined after column chromatography. The main compound corresponds to chondroitin

Fig. 1. Patterns of urinary acid mucopolysaccharides in normal persons (top,  $n=8$ ) and patients with mucopolysaccharidoses. Middle, polydystrophic oligophrenia (type Sanfilippo) ( $n=1$ ); bottom, gargoylism ( $n=4$ ).

sulphate A (CSA) (mean value, 58.5 per cent), while chondroitin sulphate B (CSB) (mean value, 14 per cent) and heparitin sulphate (HMS) (mean value, 27.5 per cent) are excreted in smaller amounts. It should be borne in mind, however, that the chromogenicity in the carbazole reaction of CSB is about one third that of CSA. Similar results of AMP excretion determined by different methods in normal persons have been reported in the literature<sup>6</sup>.

Table 2 contains the percentages of urinary AMP in four patients with gargoylism and one patient with polydystrophic oligophrenia (type Sanfilippo). The two disease states reveal a distinctly abnormal AMP excretion. The different patterns, in fact, seem to be pathognomonic of the respective mucopolysaccharidoses. In typical gargoylism HMS (53.6 per cent) and CSB (25.2 per cent) are the main urinary AMP, while polydystrophic oligophrenia is characteristically associated with a predominant HMS excretion (94.3 per cent). Fig. 1 shows a schematic drawing of the different AMP excretion patterns in normal

individuals and patients with mucopolysaccharidoses. According to our present experience the urinary AMP pattern is of valuable assistance in the diagnosis of some hereditary bone dysplasias. In addition it affords certain clues as to their basic biochemical defect.

Fractionation of urinary mucopolysaccharides was achieved by the following procedure: dialysis of the urine; precipitation with cetyltrimethylammonium bromide; washing of the precipitate with 95 per cent ethanol; column chromatography on 'Dowex 1 X 2'; and colorimetric determination of hexuronic acid and/or neutral sugar content of each fraction.

Eight normal persons of various ages revealed the following mean excretion of acid mucopolysaccharides: heparitin sulphate, 27.5 per cent; chondroitin sulphate A, 58.5 per cent; chondroitin sulphate B, 14 per cent; keratan sulphate, trace. The values are expressed in percentages of total carbazole and anthrone material eluted from the columns. In four patients with gargoylism the mean excretion was as follows: heparitin sulphate, 53.6 per cent; chondroitin sulphate A, 21.2 per cent; chondroitin sulphate B, 25.2 per cent. One patient with polydystrophic oligophrenia excreted heparitin sulphate almost exclusively (94.3 per cent).

I think that the urinary mucopolysaccharide pattern is pathognomonic of certain hereditary bone diseases and may serve as an aid in their diagnosis.

This investigation was supported by a grant from the Deutsche Forschungsgemeinschaft, Bad Godesberg, which is gratefully acknowledged.

### Disk Electrophoresis of Acid Mucopolysaccharides

WITHIN the past four years the application of disk electrophoresis for the separation of serum proteins<sup>1</sup> and lipoproteins (S. Lakshmanan, personal communication, 1966) has become more prevalent. The present report deals with the application of disk electrophoresis to the separation of acid mucopolysaccharides, in particular chondroitin sulphate B (CSB) and heparitin monosulphate (HMS).

Purified CSB and HMS which were homogeneous to paper chromatography and moving boundary electrophoresis were applied to gel columns separately and as a mixture. Acid mucopolysaccharides obtained from the urine of Hurler's syndrome patients were also investigated. Paper chromatography, moving boundary electrophoresis and uronic acid determination revealed the polysaccharide

Fig. 1. Disk electrophoresis of acid mucopolysaccharides. a, CSB; b, HMS; c, Hurler's AMPS, 60 per cent CSB, 40 per cent HMS.

from one of these patients to consist of 60 per cent CSB and 40 per cent HMS.

A 'Canalco' disk electrophoresis apparatus was used. The polyacrylamide gel was prepared in the conventional fashion. The buffer used consisted of: *tris*-3.0 g, glycine—14.4 g, diluted to 1 l. The electrophoresis was run at a current of 5 m.amp/column, and no interference resulted from the use of tracking dye. The disks were identified by staining with a solution of 1 per cent toluidine blue in 3.5 per cent acetic acid for 1 h, and subsequent destaining.

The electrophoresis of homogeneous CSB resolves two bands as shown in Fig. 1a. A slow moving major component (CSB-2) and a fast moving component (CSB-1) are separated. Similar results are obtained with HMS. In this case the major component is fast (HMS-1) and the minor component (HMS-2) is slow. Calculation of the  $R_F$  indicates that HMS-2 and CSB-1 have the same rate of migration in the buffer system employed. Electrophoresis of a mixture of CSB and HMS results in the resolution of three bands. The same result is obtained from the electrophoresis of mucopolysaccharide from a Hurler's patient (Fig. 1c).

These data, as well as others conducted in this laboratory, indicate that this is not an artefact caused by the procedure. Cifonelli and Dorfman have demonstrated that small amounts of iduronic acid may be found in HMS<sup>2</sup>. If the additional bands demonstrated by the method are not impurities it is possible that the component common to CSB and HMS contains iduronic acid. One is tempted to speculate further that the region of the glycopeptide linkage of mucopolysaccharides may be found in this common component.

The samples of CSB and HMS were given by Dr. A. Stone. I wish to thank Dr. S. Lakshmanan for his encouragement and great interest.

# Maturation of Low Molecular Weight RNA in Tumour Cells

INVESTIGATIONS carried out *in vivo* on the methylation of RNA in Krebs II ascites tumour cells using  $^{14}\text{C}$ (methyl)-L-methionine as donor of methyl groups have demonstrated that only nascent RNA is methylated<sup>1</sup>. Of the high molecular weight RNA species, both ribosomal components as well as the 35S ribosomal precursor species are extensively methylated<sup>1</sup>. In this investigation, gel filtration was employed to separate the small molecular weight RNA components, and the results demonstrate the possibility that several steps are involved in the biogenesis of low molecular weight RNA.

Krebs II ascites tumour cells were suspended in Hanks medium, supplemented with horse serum, as described previously<sup>1</sup>. After incubation with appropriate additions, the cells were removed from the medium, the RNA was extracted using a cold phenol procedure (our unpublished work), and subjected to gel filtration using 'Sephadex G-100' following the method of Galibert *et al.*<sup>2</sup>, so that a separation of ribosomal RNA (30S and 19S), which is excluded from the column, from the 5S (ribosomal) and 4S (transfer) RNA species was achieved (Fig. 1). Other investigations<sup>3,4</sup> appear to rule out the possibility that the 5S RNA component is a precursor of 4S RNA, although it has a reasonably similar base composition to 4S RNA and is devoid of pseudouridine residues and any of the methyl bases.

The tumour cells were incubated for various times with  $^3\text{H}$ -uridine and  $^{14}\text{C}$ (methyl)-L-methionine in the presence of large amounts of non-radioactive cytidine (to

prevent the conversion of  $^3\text{H}$ -uridine to  $^3\text{H}$ -cytidine derivatives within the cell) and formate (to prevent the equilibration of the methyl group of the input L-methionine with the one-carbon unit pool<sup>5</sup>). When RNA was extracted after a short period of incubation, such as 5 min, radioactivity derived from tritiated uridine was found in positions corresponding to ribosomal, 5S and 4S RNA. In addition there were peaks of relatively high activity eluting in positions between 5S and 4S RNA (peaks C and D in Fig. 1a). By comparison, the tritium radioactivity corresponding more closely to the 4S material (for example, peaks E, F and G in Fig. 1a) was relatively low. From Fig. 1a, it can also be seen that practically no incorporation of methyl groups from labelled (methyl)-L-methionine could be found in the 5S region although some could be found in the regions of peaks D, E, F and G. At this stage, however, the ratio of RNA methylation to RNA synthesis (ratio of carbon-14 radioactivity to tritium radioactivity) is low.

When the time of incubation was increased to 20 min more tritium radioactivity was present in all fractions, especially those corresponding to 4S material (regions E, F and G of Fig. 1b), and there was greater methylation of these RNA species. After 45 min the tritium radioactivity associated closely with the main RNA species (Fig. 1c) and while negligible methylation of 5S RNA could be detected, the number of methyl groups per unit length of newly synthesized RNA in the 4S region is now considerable.

It is possible that the peaks of tritium radioactivity which occur between the 5S and 4S RNA species in short-term labelling experiments represent "methyl-deficient"

Fig. 1. Elution profiles of Krebs II ascites tumour cell RNA from 'Sephadex G-100' in 0.05 molar ammonium acetate pH 5.1, after labelling the cells with tritiated uridine, 3.3 c./mmole (10  $\mu\text{C}$ /ml.) and  $^{14}\text{C}$ (methyl)-L-methionine, 29.5 mc./mmole (1  $\mu\text{C}$ /ml.) at 37° C in the presence of 1 mmolar of cytidine and 20 mmolar of sodium formate for (a) 5 min, (b) 20 min, (c) 45 min, (d) 5 min followed by the "actinomycin-pulse" and "chase" described in the text, (e) 60 min in the presence of 50  $\mu\text{g}$ /ml. of puromycin, (f) 45 min after an initial preincubation with DL-methionine (10 mg/ml.) for 30 min. Each fraction was first assayed for extinction at 260 m $\mu$ , the pH adjusted with *tris* buffer to pH 8.5, incubated at 37° C for 30 min to hydrolyse the amino acyl ester bond of any  $^{14}\text{C}$ -methionyl-SRNA present<sup>1</sup>, acidified with 5 per cent trichloroacetic acid, the acid insoluble radioactivity collected on 'Millipore' filters and assayed using a liquid scintillation counter. Extinction at 260 m $\mu$ , —; tritium radioactivity, ---; carbon-14 radioactivity, ....

intermediates in a process leading to the formation of 4S RNA, which, by virtue of a looser secondary structure, are less effectively retained by columns of 'Sephadex G-100'. To evaluate this, a "chase" type of experiment was carried out. The tumour cells were labelled for 5 min, treated with actinomycin D (50 µg/ml.) for 15 min to inhibit synthesis of 5S and 4S RNA, washed twice and finally suspended in fresh medium containing large amounts of non-radioactive uridine (0.1 mmolar), L-methionine (0.1 mmolar), cytidine (1 mmolar) and sodium formate (20 mmolar) and incubated for a further 1 h. This "actinomycin-pulse" before the "chase" procedure is required with these tumour cells to obtain maximal blocking of RNA synthesis, because it is difficult to dilute the radioactivity in the nucleotide precursor pools sufficiently quickly. The result of this type of experiment is shown in Fig. 1d, and demonstrates that the level of tritium radioactivity eluting in the region corresponding to 4S RNA after the "chase" correlates well with a redistribution of the radioactivity which originally appeared, for example, in the C and D regions after 5 min of incubation (Fig. 1a).

If the additional components (peaks C and D) represent intermediate steps of a process leading to the "maturation" of 4S RNA, the question arises as to whether or not a puromycin-sensitive step is involved, as seems to be the case in the process leading to the synthesis of ribosomal RNA from precursor RNA (refs. 6 and 7). When the incubation of the tumour cells was carried out in the presence of puromycin the "maturation" process appeared to be unaffected (Fig. 1a), although the radioactivity in the excluded ribosomal peak was reduced.

It seemed also of interest to determine to what extent the process depended on methylation of RNA. Previous treatment of the tumour cells with DL-ethionine was sufficient to depress, by about 75 per cent, the subsequent incorporation of labelled methyl groups from labelled (methyl)-L-methionine into RNA. Presumably this was because enough S-adenosylethionine<sup>8,9</sup> was formed within the cells to impair either the formation, or functioning, of S-adenosyl-L-methionine, the donor of methyl groups to RNA. The pattern of incorporation of label from tritiated uridine added after the preincubation period with DL-ethionine indicates that the "maturation" process was only slightly impaired, which suggests that, although possibly a number of steps are involved in the biogenesis of 4S RNA in Krebs II ascites tumour cells, insertion of methyl groups appears to be a refinement rather than an obligatory step, although there is some evidence from bacterial systems that "methyl-deficient" transfer RNA has altered physical properties<sup>10</sup>.

## IMMUNOLOGY

### Action of Disinfectants on Experimental Mouse Scrapie

Mouse adapted scrapie, a progressive degenerative disease of the central nervous system, appears to be unusually resistant to heat and exposure to formalin. In view of this, it was decided to attempt to kill the experimental scrapie infectious agent by treating with some disinfectants, such as alcohol, a hypochlorite, a surface-active agent, and the agent was also boiled for 60 min. A 1:10 w/v suspension of mouse brain infected with scrapie was mixed with an equal volume of the suitably diluted disinfectant and the mixtures were kept overnight at +4° C before female mice (18–20 g) were inoculated by the subcutaneous route. Each 0.5 ml. dose of the mixture contained 0.25 ml. of the infective material. Controls were inoculated with disinfectants and scrapie suspension. An additional control group was inoculated with 0.03 ml. of scrapie intracerebrally to give an early indication of the pathogenicity of the scrapie agent; the incubation period in mice was considerably shorter by this route<sup>1</sup>.

Table 1

Material inoculated	Total No. of mice inoculated	Total No. of survivors	Percentage of survivors at 9 months
Scrapie and 2 per cent surface-active agent	16	5	31
Control	12	12	100
Scrapie and 50 per cent alcohol	16	0	0
Control	11*	9	82
Scrapie and 2 per cent hypochlorite	16	15	94
Control	16	13	81
Scrapie boiled 1 h	15*	14	93
Scrapie only, intracerebral route	6	0	0
Subcutaneous route	28	7	25

\* Denotes one mouse died within a few days of inoculation and was not included in the result.

The mice were kept for 9 months and all mice dying with an illness typical of scrapie within the average incubation period for the disease were considered to have died from scrapie. A random brain sample was examined histologically to confirm the diagnosis.

A summary (Table 1) of the results of two experiments using either BSVS or MRCTO mice showed that a 2 per cent hypochlorite solution killed the infectious agent, and so did boiling for 60 min. The surface-active agent and alcohol, however, were not effective in the concentrations used.

### Specific Antigenicity of Thymocytes

THYMOCYTES (thymic lymphocytes) are believed to differ from lymphoid cells of other organs. They show a different response to a variety of physical, chemical and biological stimuli<sup>1</sup>, such as irradiation<sup>2</sup> and phytohaemagglutinin<sup>3</sup>, and it has been claimed that they have an epithelial rather than mesenchymal origin<sup>4</sup>. In the mouse, autoantibodies<sup>5</sup> and isoantibodies<sup>6,7</sup> have been demonstrated with a selective toxic effect on thymocytes. The present investigation with a heterologous thymus-specific antiserum reveals rat thymocytes differing antigenically from the lymphoid cells of lymphatic circulation, lymph node and spleen.

Thymuses of 5-7 week Lister hooded rats were homogenized and fractionated to obtain microsomal material<sup>8</sup>. This was then identified by electron microscopy, whereby the presence of endoplasmic reticulum vesicles and ribosomes was confirmed while mitochondrial and nuclear contamination were not detected. The preparation was incubated at 37° C because autolysis had previously been shown to facilitate solution of microsomal antigens<sup>9</sup>. The yield from 15 g of thymus tissue (seventy-five rats) was 90 mg of microsomal protein, the concentration of which was adjusted with physiological saline to 2 mg of protein/ml.

Because the microsomal antigen was in such short supply, mice (*BALB/c*) were chosen as the source of antisera. Six mice were immunized over a period of 5 weeks by weekly intraperitoneal injections of 0.25 ml. of the microsomal preparation (that is, 0.5 mg of protein). One week later they were given a subcutaneous injection of the same dose of antigen and, to stimulate ascites as an abundant source of antibody, 0.5 ml. intraperitoneally of Ehrlich ascites tumour, also from *BALB/c* mice. Ten days later the peritoneal exudate was tapped, centrifuged to remove the clot, and the globulin-rich supernatant ("antiserum") stored frozen. The antiserum was found to be immunologically active by immunofluorescence, but it gave no precipitin lines when tested by gel diffusion against the thymus antigen. Absorptions of the antiserum were carried out by shaking with a half volume of rat organ homogenate for 2 h at room temperature followed by centrifuging.

Immunofluorescent staining with general procedures and controls described elsewhere<sup>10</sup> was effected by the "sandwich" method with fluorescein-labelled horse anti-mouse globulin absorbed with rat tissue homogenates. Preparations of rat thymus for immunohistological examination included unfixed frozen sections, smears and impression films, of which the latter gave the most satisfactory results. They were made by touching a chemically clean microscope slide with the cut surface of a fresh thymus and drying overnight with a fan (at 2° C). Before staining they were washed by gentle shaking for 15 min with phosphate-buffered saline (0.1 molar phosphate, pH 7.1), drained, and then treated with a drop of "antiserum" for 30 min. After rinsing and washing for 10 min in two changes of buffered saline, they were stained with the conjugate, again washed and mounted in buffered glycerol. Microscopical preparations were examined not more than 2 h after mounting, because staining deteriorated rapidly, being largely dissipated after standing overnight.

The unabsorbed antiserum gave diffuse staining of rat connective tissue and parenchymal organs, and the reaction was intense with all the lymphoid organs; skeletal muscle fibres did not stain. After absorption by rat liver homogenate, the serum stained only the lymphoid organs (Table 1). Further absorption with circulating lymphocyte microsomes or lymph node or spleen homogenates made the serum fully thymus-specific, when it stained the cytoplasmic rim of thymocytes only (Fig. 1). The staining often had a distinct granular pattern. It was not affected by serum absorption with rat skeletal muscle or

Fig. 1. Unfixed impression film of thymus treated first with mouse anti-rat thymus microsome serum absorbed with rat liver and lymph node homogenates, and second, with fluorescein-conjugated horse anti-mouse globulin. Many thymocytes show fluorescent staining limited to the cytoplasmic rim. Other cells recognizable by autofluorescence only. ( $\times 470$ .)

brain homogenates, but it was completely inhibited after absorption with thymus homogenate.

The histological distribution of thymus-specific staining could not be assessed with certainty in the impression films, but it was largely located in the cortical thymocytes. Some thymocytes failed to stain as could be judged by combined fluorescence and phase-contrast microscopy and no specifically stained non-lymphoid cells could be identified. Hassall's corpuscles gave bright non-specific staining with the conjugated antiglobulin serum alone; there was no evidence of specificity of reaction with the anti-thymus serum.

Our findings indicate that there are at least two special antigens in the cytoplasm of the majority of thymocytes. One, common to all lymphocytes, could be demonstrated in frozen sections, films and smears, and its corresponding antibody could be neutralized by absorption with circulating lymphocytes, lymph node or spleen. The second, more soluble, could be detected only in whole thymocytes either in films or smears and its corresponding antibody could be neutralized by absorption with thymus homogenate only. The cells containing both antigens were morphologically indistinguishable from those with only the common lymphoid antigen. Further work is required to determine whether these two cell types represent original and immigrant<sup>11</sup> populations of the thymus. The possibility that the antigenic difference reflects immunological commitment should also be explored.

## Correlation between "Methicillin Resistance" and Serotype in Staphylococcus

"METHICILLIN resistance" has been found in a number of strains of staphylococcus isolated in French hospitals. Chabbert and Baudens<sup>1</sup> found in 1961 that ten of eighty-two strains investigated (12 per cent) were resistant to methicillin. In 1962 they found twenty-one resistant strains out of 127 (17 per cent), and in 1963 twenty-six out of 134 (19 per cent)<sup>2,3</sup>. Courtieu *et al.*<sup>4</sup> found a similar picture in their investigation of hospitals in other parts of France. In 1964 they found thirty-one resistant strains out of 216 (14 per cent). The frequency found in France seems to be different from that found among strains isolated in England and the United States<sup>5-8</sup>.

Serological typing of staphylococcus has been carried out in France by the slide-agglutination technique since 1950<sup>9-12</sup>. Using this technique, Pillet *et al.* have developed the work of Cowan<sup>13</sup>, Christie and Keogh<sup>14</sup> and Hobbs<sup>15</sup> to show that the predominant serotype of staphylococcus in French hospitals before 1960 was serotype III. They then began to find a new type of hospital staphylococcus emerging, namely, type 14. Since 1963/64 this type is replaced by yet another, type 18, which is now prevalent. Although it is easy to obtain specific monovalent sera of types III, 14 and 18, there are antigenic relationships between strains of type III and 14 and also between strains of type 14 and 18. Furthermore, staphylococci belonging to serotypes III, 14 and 18 are usually lysed by group III phages.

We have therefore attempted to determine the correlation between agglutination serotype and methicillin resistance for various strains of staphylococcus.

We have investigated the serotype of ninety-nine strains isolated in 1965 from ten hospitals in Paris. Twenty-one of these strains belonged to serotypes I and II, twenty-eight to serotype III, seven to serotype 14, and forty-three to serotype 18.

The minimum inhibitory concentrations were determined using the agar streak method, using an inoculum consisting of one-hundredth of an overnight culture, on trypticase soy agar with 5 per cent added sodium chloride. This proportion of sodium chloride allows the phenotypic expression of methicillin resistance<sup>16</sup>.

The results obtained with methicillin are shown in Table 1 and those with cephaloridin in Table 2. Both tables clearly show that twenty out of twenty-one strains of serotypes I and II and seven out of seven of serotype 14 are inhibited in these conditions by 8 µg/ml. or less of methicillin and by 2 µg/ml. or less of cephaloridin; these strains are sensitive. Conversely, the forty-three strains of serotype 18 are inhibited by 16 µg/ml. or more of methicillin and 4 µg/ml. or more of cephaloridin. These strains can be classified as resistant. The twenty-eight strains of serotype III are inhibited by various concentrations.

These results show clearly that all the strains belonging to serotype 18 are "methicillin resistant". But the resistant strains may also belong to serotype III. This probably means that there is no linkage between the

genes responsible for serotype and resistance. A greater frequency of mutants resistant to β-lactam ring antibiotics (penicillins and cephalosporins) would be observed in this serotype. In any case, "methicillin resistant" staphylococcus serotype 18 has shown a particular ability to be selected in French hospitals. It would be interesting to investigate its prevalence in other countries.

## MICROBIOLOGY

### Mutation of Bacterial Cells by Controlled Desiccation

PREVIOUS work has established reasonably well that the reorientation or removal of water molecules bound to macromolecules may result in the loss of viability and infectivity of bacterial cells and virus particles<sup>1</sup>. During the above studies when auxotrophic cells were held at certain levels of relative humidity (RH), prototrophic mutants were found, apparently produced as a direct result of desiccation. Later the mutation of bacterial cells by ultra-violet light was found to be more easily achieved if the cells were partially desiccated at 40 per cent RH (ref. 2), indicating that bound water molecules played some part in the mechanisms responsible for mutation. Cells or virus particles held at RH levels between 80 and 30 per cent contain from 35 g water/100 g of cell solids (35 per cent water) to 3 per cent water<sup>1</sup>. Because 30–40 g water/100 g of solid is just sufficient to hydrate fully protein RNA and DNA, desiccation below 80 per cent RH affects only the quantity of bound water in the cell. The apparent mutation of cells from desiccation suggested that water molecules were, in part, responsible for maintaining the biological integrity of DNA, and therefore further studies were warranted. It is the purpose of this paper to present the results of preliminary investigations.

Cells of *Escherichia coli* B were grown at 37° C in 'Bacto' brain-heart infusion broth, supplemented with 0.5 per cent yeast extract. After 12 h or 48 h of growth the cells were gathered by centrifugation, washed once in de-ionized water and resuspended in 20 ml. of water or 5 per cent w/v *D*-inositol. The latter compound was used because it had been found previously to prevent the death of cells by desiccation<sup>1</sup>. Oxygen free nitrogen gas was bubbled through the cell suspension for 1 h and the cells were then atomized with nitrogen in a rotating steel drum which contained nitrogen. In the drum the temperature was maintained at 25° C and the relative humidity was preset by spraying water free of oxygen into the drum,

and measuring the relative humidity with a 'Serdex' membrane RH meter. The spray device generates droplets of 10  $\mu$  mean mass diameter which evaporate within 0.2 sec (ref. 3). The atomized cells were held for 60 min and then 10<sup>7</sup> cells/ml. were collected in a liquid impinger containing 8.0 ml. of 1.0 per cent glucose in 0.85 per cent chloride sodium. Immediately after collection, 2.0 ml. of double-strength yeast extract was added and the cells incubated at 37° C for 90 min. The cells were then sedimented by centrifugation, washed once in saline, and then starved for 30 min in 0.1 molar phosphate buffer, pH 6.8. After starvation the cells were resuspended in 10 ml. of a minimal salts medium<sup>4</sup>, 1.0 ml. was removed, serial ten-fold dilutions in saline were made and viable cell counts determined by plating 0.2 ml. of each dilution on to agar with yeast extract. The cells in the remaining 9.0 ml. were sedimented, resuspended in 9.0 ml. of the minimal salts medium containing 0.6 molar sucrose and 0.01 molar magnesium sulphate, and incubated at 37° C on a shaker for 90 min<sup>5,6</sup>. Then 0.1 ml. of a solution containing 100,000 units of penicillin/ml. was added and the cells incubated for a further 90 min without shaking. The treated cells were sedimented, washed and resuspended in 9 ml. of sterile water. Aliquots of 0.2 ml. were then spread on to an outgrowth minimal medium agar supplemented with 1.0  $\mu$ g/ml. of twelve amino-acids and 0.5  $\mu$ g/ml. of the five nucleic acid bases and six vitamins. Auxotrophic cells on such a medium tend to produce very small colonies and surviving prototrophic cells large ones. After 36 h at 37° C, the colonies were picked off and the cells suspended in 5 ml. of sterile saline. The cells in each suspension were spotted on to minimal agar and three types of enriched minimal agar each containing one of the following: (a) 0.5 per cent amino-acids free of vitamin; (b) 100  $\mu$ g/ml. of the five nucleic acid bases; and (c) 20  $\mu$ g/ml. of six vitamins. After 36 h of growth, cells forming colonies on one of the three enriched media but not on the minimal medium were considered to be auxotrophic mutants. To serve as controls, a dilution of the cells remaining in the spray bottle after atomization containing approximately  $1 \times 10^7$  cells/ml. was made in glucose-saline and treated in the same way as the desiccated ones. Three experiments at 30, 40, 55 and 75 per cent RH with both log phase and stationary phase cells and two with inositol at 40 and 55 per cent RH were conducted. Results were calculated on the basis of number of mutant colonies/ $1 \times 10^6$  viable cells.

The number of large colonies formed on the outgrowth medium accounted for less than 1.0 per cent of the total and all except one contained prototrophic cells; also, of the smaller colonies, 32 per cent were found subsequently to be prototrophic. From the results shown in Tables 1 and 2, for stationary phase and log phase cells respectively, it is clear that auxotrophic mutants were more plentiful in the cells surviving desiccation at RH levels below 55 per cent RH. With stationary phase cells the maximum number occurred at 40 per cent RH and with log phase cells at 55 per cent RH. Moreover, when inositol was used to protect the cells against loss of viability, the number of mutants was considerably reduced, particularly with cells in the stationary phase of growth.

It has been known for a number of years that sometimes when freeze-dried or dried stock cultures are rehydrated the culture possesses different characteristics from those of the original strain and it has been argued that mutant cells may be more resistant to the treatment and, therefore, are selected. While investigations to date do not disprove this theory, in order to explain the presented results in the same terms, it is necessary to postulate that (a) auxotrophic cells are more resistant to desiccation at 55 per cent RH and below than the parent cells, and (b) inositol is not as efficient a stabilizer of mutants as it is of the parent cell. Both notions appear unlikely because prototrophic cells are produced from auxotrophic ones during desiccation below 55 per cent

RH, and in previous work carried out over the past 10 yr the ability of inositol to protect cells has been found to be independent of the strain of organism used. The pronounced dependence of mutant numbers on the RH at which the cells were held suggests that the removal or reorientation of bound water molecules is mutagenic and there appear to be two possible explanations. One is that the removal of water allows the irreversible attachment of proteins to certain gene sites and the other that changes in DNA structure occur as a result of partial desiccation. The former suggestion cannot be discounted, but seems improbable because there is no experimental evidence to support it at this time. The latter hypothesis is favoured because the structure of DNA is known to rely on bound water<sup>5</sup> and because at 55 per cent RH the water lattice of DNA is broken and water bound to  $=P=O$  or  $=C=O$  only is present<sup>5</sup>. It therefore seems reasonable to suggest that interactions between the desiccated  $-N$ ,  $-NH$ ,  $NH_2$  and  $-OH$  groups and the partially hydrated  $=P=O$  and  $=C=O$  groups will occur. In addition, water orientated by hydrophobic groups which normally assist in maintaining the structure of macromolecules will be absent. Such interactions will distort the DNA molecule and could result in irreversible changes, especially if the DNA is replicating and in the open stranded state. The higher incidence of mutations in log phase cells is considered, therefore, to be caused by a greater sensitivity of the DNA to desiccation when it is replicating, and the

reduced incidence at 30 per cent is thought to reflect a more severe damage leading to cell death rather than to mutation. Further evidence to support the water reorientation hypothesis comes from work in which inositol has been shown to prevent X-ray and ultraviolet damage to semi-dried cells by apparently taking on the role of the bound water removed by desiccation<sup>1</sup>, and desiccation alone to induce the prophage in lysogenic cells<sup>2</sup>. The latter finding strongly indicates that desiccation does affect the biological integrity of DNA.

In order to test the validity of the hypotheses presented, the desiccation sensitivity of some twenty mutants is now being determined. To date, the mutant cell appears to have either the same sensitivity or to be more sensitive than the parent cell. It will, however, be some time before all the strains have been examined, but if mutagenesis by desiccation can be substantiated it could be a useful tool in experimental genetics.

### Ectotrophic Mycorrhizae as Deterrents to Pathogenic Root Infections

MANY investigators have demonstrated the importance of ectotrophic mycorrhizae in the growth of trees. The role of these structures is physiological: mycorrhizae increase the absorbing surface area of roots; they exert a more selective ion absorption and accumulation, and they make very slightly soluble substances in soil available to their host. Another function has been postulated by Zak<sup>1</sup>, who suggested that ectotrophic mycorrhizal roots may be less susceptible than non-mycorrhizal roots to infection by root pathogens. He proposed several mechanisms by which these structures could be resistant to pathogenic infections.

We have found evidence to support this hypothesis. Mycorrhizal and non-mycorrhizal roots attached to potted shortleaf pine (*Pinus echinata* Mill.) seedlings grown in finely divided shortleaf pine humus were enclosed in small glass cells and inoculated with zoospores (20,000/ml.) of *Phytophthora cinnamomi* Rands. After incubation for 10 days in a growth chamber the roots were examined histologically. Results indicated that mature mycorrhizae were resistant to infection, whereas non-mycorrhizal short roots and lateral root tips were highly susceptible (Table 1).

Table 1. INFECTION AFTER 10 DAYS BY *Phytophthora cinnamomi* OF ROOTS OF SHORTLEAF PINE SEEDLINGS GROWN IN HUMUS IN GREENHOUSE POT CULTURE

Series	Mycorrhizal roots		Non-mycorrhizal short roots		Non-mycorrhizal lateral root tips	
	No.	Per cent	No.	Per cent	No.	Per cent
Inoculated	58		27		12	
Infected		0		100		100
Non-inoculated	38		16		9	
Infected		0		0		0

Similar results were obtained using detached mycorrhizae on lateral root segments of shortleaf pine seedlings, and intact mycorrhizae synthesized aseptically with different mycorrhizal fungi on roots of seedlings of shortleaf and loblolly pine (*Pinus taeda* L.). We concluded that ectotrophic mycorrhizae on roots of shortleaf and loblolly pine are protective barriers to pathogenic

infection by *P. cinnamomi*. In field conditions, one could expect trees with abundant development of mycorrhizae to have less susceptible root tissue exposed to *P. cinnamomi*, and perhaps other root pathogens, than trees with few or no mycorrhizae. This work is being extended and will be published in detail later.

## PATHOLOGY

### Aetiological Significance of Rod-shaped Bodies in Rheumatoid Synovia

IN recent years there has been renewed interest in the old rejected notion that rheumatoid arthritis may be caused by an infectious agent<sup>1</sup>. Highton *et al.*<sup>2,3</sup> have reported rod-shaped bodies in the synovial vessels of four out of seven rheumatoid patients and two out of six patients with Reiter's disease. No such bodies were found in seven normal or near-normal synovia. These authors have therefore suggested that "these intracellular rod-shaped inclusion bodies found in endothelial cells and pericytes of synovial blood vessels may be phases of an infective agent".

During the course of our investigations of the ultrastructure of normal and pathological synovia<sup>4,5</sup> we have frequently seen these rod-shaped bodies in vascular

Fig. 1. Rod-shaped bodies (R) in synovial vascular endothelial cell from a case of traumatic arthritis. (×48,000.)

endothelium. Since the publication of the paper<sup>2</sup> by Highton *et al.*, we have re-examined some of our material and have found these bodies in the synovial vessels of five out of six cases of rheumatoid arthritis, six out of six cases of osteoarthritis, five out of six cases of traumatic arthritis and three out of four normal or near-normal human synovial membrane. We have also seen these bodies in five out of six normal rat synovia.

Our observations obviously reveal a state of affairs quite different from that described by Highton, and one must ask whether we are all investigating the same structure.

Weibel and Palade<sup>6</sup> described rod-shaped bodies in the vascular endothelia of various tissues of man and rat (synovium was not investigated). Highton *et al.*<sup>2</sup> considered that the rod-shaped bodies which they had observed in the capillaries of rheumatoid synovia were different from those seen by Weibel and Palade<sup>6</sup>. We cannot accept this view, for the bodies seen by us, by Highton and by Palade are of similar morphological appearance and size. Thus the rod-shaped bodies (Fig. 1) in our specimens measure approximately 0.1  $\mu$  in diameter, as also do the bodies described by Highton and Palade. Further, in all these investigations these bodies are seen to be bounded by single membranes and to contain tube-like structures of approximately 150 Å in diameter.

Thus it is obvious that we are all referring to the same structure and that it is widely distributed in a variety of normal and pathological tissues. The nature and significance of this structure are, however, obscure. It remains for future research to determine whether this is a normal organelle found in the vascular endothelium of some species or a structure of exogenous origin which is or is not a factor in the production of some disease process in man.

### Unstable Rapidly Labelled RNA in Chronic Lymphocytic Leukaemic Cells

THE relative amounts of the various forms of RNA—namely messenger RNA, transfer RNA and ribosomal RNA—in different cells and in different phases of the cell cycle would seem to be of the utmost importance and may provide a clue to the nature of pre-mitotic events in the cell<sup>1</sup>. Information along these lines is rapidly accumulating. Various attempts have been made to characterize these RNA patterns in several mammalian cell lines, namely, the blast cells derived from lymphocytes stimulated by phytohaemagglutinin (PHA)<sup>2</sup>, the HeLa cell<sup>3</sup> and cells from a variety of pathological processes<sup>4</sup>.

Recently, Storti and Torelli<sup>5</sup>, using autoradiographic techniques and performing actinomycin D chase experiments on normal myeloid cells and myeloblastic leukaemic cells, have determined the relative amount of rapidly labelled unstable RNA (messenger RNA?) in these cells. There appeared to be no unstable RNA in the myeloblastic leukaemic cells compared with substantial amounts in the normal myeloid cells. This is a provocative finding because investigations of other mammalian cells have shown that some unstable rapidly labelled RNA is always

present. It seemed to us that it would be of interest to repeat these observations on other forms of leukaemia in man.

We chose to study the cells from patients with chronic lymphocytic leukaemia (CLL) because they are easily obtained from patients and because recent studies<sup>6</sup> have shown that there is good reason to believe that the response of the chronic lymphocytic leukaemic cell population to PHA is a measure of the proportion of abnormal cells to normal cells. Each sample can therefore be tested by exposing it to PHA and the proportion of PHA blast cells that result in 72 h ascertained. If the conversion is very low, it can reasonably be assumed that the population of abnormal cells obtained is relatively homogeneous. A further reason for our choice was that we and others<sup>7</sup> had found that RNA synthesis in CLL cells occurs in a fairly brisk fashion as judged by the uptake of tritiated uridine when cells are flash labelled. Moreover, we chose to obtain these quantitative data by liquid scintillation counting methods combined with autoradiography.

Cells from patients with chronic lymphocytic leukaemia were obtained from their peripheral blood by collecting it in dextran and heparin and allowing the erythrocytes to settle. The lymphocytes from the supernatant were suspended in tissue culture medium T.C. 199 (Glaxo) and normal AB serum at a concentration of 25 per cent (2–3,000 cells/mm<sup>3</sup>). A total of seven patients were chosen on the basis that their lymphocytes showed less than 15 per cent (one case 27 per cent) blast cell conversion in the presence of phytohaemagglutinin after culture for 72 h (Table 1).

Table 1

Patient and time cells in culture before study (h)	Peripheral blood WBC $\times 10^3$ mm <sup>3</sup> at time of study	Percentage of blast cells after 72 h culture with PHA	Treatment at time of study

72			

\* Same patient sampled on two separate occasions.

Peripheral blood from normal human donors was obtained and mixed with heparin and PHA (Difco), 0.1 ml./5 ml. of blood. The erythrocytes were allowed to settle and the supernatant rich in white cells was diluted in T.C. 199 and AB serum (75 : 25) (cell concentration of 1–2,000 cells/mm<sup>3</sup>). Additional PHA M was added at a concentration of 0.1 ml./5 ml. of culture. The cells were collected after 72 h and treated in the same manner as the cells from the chronic lymphocytic leukaemic patients.

The CLL cells without PHA and the 72 h PHA blast cells were studied in the following manner: The cells were exposed to uridine-5-<sup>3</sup>H (specific activity 5,000 mc./mmole) at a concentration of 2–10  $\mu$ Ci/ml. of culture for 1 h. The cells were either washed once and resuspended in normal media with "cold" uridine at a concentration of 1 mmolar and actinomycin D (10  $\mu$ g/ml., kindly supplied by Merck, Sharp and Dohme) or actinomycin D 10  $\mu$ g/ml. was added directly to the cell culture without washing. The former will be referred to as a washed chase and the latter as an unwashed chase. At the time of addition of actinomycin D and at subsequent intervals thereafter, duplicate samples were taken for extraction of RNA and liquid scintillation counting as well as for the preparation of autoradiographs.

One millilitre of culture material was immediately placed in an ice bath. This was done in a duplicate fashion at each appropriate interval. The duplicate

samples were centrifuged for 10 min at 2,500 r.p.m. and 1 ml. of 0.5 normal perchloric acid<sup>8</sup> was added to the cell button. This was centrifuged for 10 min at 2,500 r.p.m. and washed with 0.5 normal perchloric acid. The cell precipitate was collected by centrifuging and to it was added 1 ml. of 0.3 normal sodium hydroxide. The precipitate was agitated and dissolved in the sodium hydroxide, and then incubated at 37° C for 1 h. It was then removed, placed in an ice bath, and 2 ml. of 0.5 normal perchloric acid added. The supernatant containing the RNA fraction was obtained after separation by centrifuging for 10 min at 2,500 r.p.m. This was then stored at 4° C until it was counted in the liquid scintillator.

Autoradiographs were prepared at the same times by smearing cells on an ordinary slide, staining by the periodic acid-Schiff reaction, then immersing the slides in Kodak 'NTB-2' emulsion, exposing them for 1, 6, 14 and 30 days, then developing and counterstaining with aqueous haematoxylin.

Grain counts were performed on fifty cells in each slide. The percentage of 500 cells labelled was ascertained and the total grain count was calculated by allowing for the background and correcting for the percentage of cells labelled.

The supernatant containing RNA was adjusted to a pH of 9 and 0.5 ml. was mixed with 10 ml. of liquid scintillator. The latter was a mixture of 2,5-diphenyl-oxazole/naphthalene/dimethyl 2-*p*-phenylenebis 4-methyl, 5-phenyloxazole in dioxan. The mixture was then placed in the refrigerator at 4° C overnight and the next morning counted in a Nuclear Chicago counter. Efficiency was determined by the multiple channels ratio method and varied between 6 and 11 per cent. All samples were extracted in duplicate and each duplicate was counted in duplicate in the counter. Results for both autoradiographic and liquid scintillation counting data are expressed as a percentage of the 1 h sample for the appropriate technique.

The PHA blast cell in the washed chase showed a 50 per cent drop in counts 1 h after addition of actinomycin D on the basis of two experiments. Four experiments with these cells in unwashed chases showed a 40 per cent drop in counts both by autoradiographic and liquid scintillation counting data. The standard deviations of the liquid scintillation counting data are shown in Fig. 1*a* and *b*. The standard deviations of the autoradiographic values ranged from  $\pm 16$  per cent to  $\pm 9.1$  per cent. The presence of cold uridine following a wash most certainly decreases continued uptake of uridine-5-<sup>3</sup>H compared with the unwashed chases<sup>9</sup>.

Four washed chase experiments were performed on CLL cells. The autoradiographic and liquid scintillation data agree remarkably and by 2 h after addition of actinomycin D reveal a 70–75 per cent drop in counts.

Unwashed chase experiments were completed on seven sets of CLL cells (three were 72 h samples). The autoradiographic data reveal a 73 per cent drop in the grain count 45 min after addition of actinomycin D (see Fig. 2*a* and *b*). The standard deviation of the autoradiographic data varied from  $\pm 22$  per cent to  $\pm 7.5$  per cent with a mean of  $\pm 15.4$  per cent. The unstable RNA appeared to be entirely nuclear in origin as determined by nuclear and cytoplasmic grain counts.

Two aspects of this investigation deserve comment. It is gratifying to see that autoradiography can be relied on to give some quantitative estimate of the metabolism of rapidly labelled cellular RNA when certain technical features are considered: namely, the adjustment of the exposure times on the autoradiographs to ensure that the number of grains is not so great as to render counting inaccurate.

Autoradiography enables us to ascertain whether the quantitative data obtained by RNA extraction procedures and liquid scintillation counting pertain to a certain type of cell identified by morphology or whether they reflect the

behaviour of the entire cell population. In this investigation, the latter appeared to be the case as virtually all CLL cells were labelled with only the occasional cell showing extremely high grain counts or none at all.

The second and more important aspect is that there appears to be a greater proportion of unstable rapidly labelled RNA in CLL cells compared with the 72 h PHA blast cell or the 1 h PHA incubated lymphocyte which has approximately 30 per cent unstable RNA (ref. 10). The populations of CLL cells studied all showed less than 0.1 per cent incorporation of tritiated thymidine and were obviously non-proliferating; whereas the PHA blast cell is rapidly proliferating. Are these differences related to phases of the cell cycle? We assume that the CLL cells are arrested in the  $G_1$  phase<sup>11</sup> or perhaps in the  $G_0$  phase, out of cycle<sup>12</sup>, and therefore differences between these cells and the 72 h PHA blast cells which are entering the S phase at a rapid rate may reflect basic differences in the RNA pattern at these various phases of cell life.

Fig. 1. Results for washed (*a*) and unwashed (*b*) chase data for 72 h PHA blast cells expressed as a percentage of the 1 h incubation value.

Fig. 2. Results for washed (*a*) and unwashed (*b*) chase for CLL cells. In all experiments, actinomycin D was added to cells after incubation for 1 h with uridine-5-<sup>3</sup>H. Time zero indicates addition of actinomycin D. ●—●, Liquid scintillation counting values with standard deviation; Δ—Δ, autoradiographic values (see text for S.D.).

These findings are dissimilar to those of Storti and Torelli working with acute myeloblastic leukaemia cells. Where we found 75 per cent unstable rapidly labelled RNA in CLL cells, they found none in the myeloblastic cells. This may reflect a basic difference in the two types of cells or again may be related to differences in phases of cell cycle. The question may be answered by the characterization of this unstable RNA according to molecular-weight before one can assume that it represents messenger-RNA, and the correlation of these changes in a more precise fashion to phases of the cell cycle.

We thank R. J. Flemans, Miss Muriel Beard and David Plumb for their skilled technical assistance.

## RADIOBIOLOGY

### Effects of Irradiation and Antigenic Stimulation on Circulating Haemopoietic Stem Cells of the Mouse

WHOLE body irradiation causes depression of haemopoiesis, and a sufficiently large dose of X-rays in an exposure of a few minutes can be effectively 100 per cent lethal. Thus, in *CBA/H* mice a dose of 1,000 rads results in aplastic anaemia, lethal within 2 weeks. Nevertheless, successful therapy is possible with intravenous injections of certain cell suspensions, some components of which act as seed for the recolonization of myeloid and lymphoid tissues<sup>1,2</sup>. The various cell lines, erythrocytic, granulocytic, thrombocytic and lymphocytic, may be restored by their respective precursors (polyphyletic hypothesis) or be derived by differentiation from a common multipotent cell (monophyletic hypothesis). In either case the precursor can be termed a stem cell.

McCulloch and Till<sup>3</sup> have made the important observation that, after the administration of such suspensions with cell numbers suboptimal for clinical recovery, examination of the spleen on about the tenth day reveals colonies which histologically are of erythropoietic or granulopoietic or thrombopoietic type: at a late stage they may be mixed<sup>4</sup>. Cytological evidence suggests that each colony represents a clone formed from a stem cell<sup>5</sup> which itself may have reproduced other stem cells<sup>6</sup>. Of the total stem cells administered only a fraction (about one-sixth<sup>6</sup>) wends its way to the spleen. These particular stem cells or colony forming units (CFU) are present in but low concentration in the effective cell-suspensions, for example, about 1/10,000 nucleated cells in normal murine bone marrow<sup>7</sup>.

Similar stem cells are present in circulating blood of normal mice, for their leucocytes in sufficiently large number can recolonize lethally irradiated mice<sup>7</sup> and produce spleen colonies<sup>8</sup>. The concentration of colony forming units, however, in peripheral blood is still lower (about 10<sup>-6</sup>) than in bone marrow.

The present note is concerned with these circulating colony forming units in mice under special circumstances.

Blood was withdrawn with a heparinized syringe by cardiac puncture from comparable mice, deeply anaesthetized with chloroform, and then pooled. After the

nucleated cells had been counted in a Bürker haemocytometer, intravenous injections of measured volumes of the blood, whole or diluted with Tyrode solution, were made into lethally irradiated syngeneic *CBA/H* mice. Each dose was given to a batch of 5–10 mice, and when practicable a range of doses in descending order from  $5 \times 10^6$ – $10^5$  nucleated cells was employed.

The recipient mice were killed after 10–11 days, the spleens were fixed in Bouin's solution and the colonies visible to the eye counted later. Mice dying between the eighth and eleventh days were also accepted if fresh and the counts in the fixed spleen used.

Table 1 shows the ratio CFU/10<sup>5</sup> nucleated cells given, and CFU/cm<sup>3</sup> of blood given, in a representative experiment involving ninety-six recipient normal mice on five different mornings. There is a variation of estimate from 0.09–0.33 (mean  $\sim 0.2$ ) in CFU ratio and from 3–17 (mean  $\sim 10$ ) in CFU/cm<sup>3</sup>.

Table 1. CFU RATIO AND CFU/CM<sup>3</sup> IN NORMAL BLOOD

\* Figures in parentheses are derived wholly or predominantly from mice dead after 8 days.

In blood, taken from irradiated mice 1, 3, 7, 10, 21, 43 and 63 days (experiment A) after receipt of a dose of 350 or 700 rads of X-rays to the whole body, the concentrations of colony forming units are compared in Table 2 with those of normal mice killed at the same time. Colony forming units detectable by the method disappear after X-irradiation and return 7–10 days later when the myeloid tissues are known to be regenerating. At that time the CFU ratio may be more than ten times greater than in normal blood, for example, values of 4.9 and 2.7 on the tenth day following 700 and 350 rads respectively compared with the average normal of 0.2 and the specific control value of 0.14. This high ratio, however, is caused by a decrease in the denominator, that is, the leucopenia, and the value of CFU/cm<sup>3</sup> of blood is around the normal 10. One high value of 46 was found later at 3 weeks after 700 rads. In a replicate experiment B, blood was taken at 7, 10 and 14 days. The results were substantially the same in controls and mice given 350 rads. In the mice given 700 rads, though no colonies were found at 10 days, there was an increase in both CFU ratio and CFU/cm<sup>3</sup> at 14 days.

Observations in this laboratory on leucocytes from immunized mice (Mayrhofer, unpublished) indicate an increase in colony forming units 7 days after an administration of pertussis vaccine with alum-precipitated calf serum by intraperitoneal and subcutaneous routes. The time-course of this response over 3 weeks is given in Table 3. (The data in Table 1 are the specific control normal animals for this experiment.) The CFU ratio is increased some ten-fold as early as the third day, is about the same at the seventh day and declines to normal values by 3 weeks. Because these values are associated with leuco-

cytosis, the CFU/cm<sup>3</sup> may be raised more than ten-fold in the peak at 7 days.

The origin of stem cells in the peripheral blood has been attributed to myeloid tissue<sup>9</sup>, because in the normal adult mouse the highest concentration of colony forming units is found in bone marrow.

The results reported here from irradiated mice support this interpretation. Extensive damage to the postulated source cut off the supply for a week. If myeloid tissue had been a site of concentration of stem cells imported via the blood stream rather than an exporting source, an increase might have been expected in the blood before regeneration of the marrow, which occurs in the first two weeks<sup>7</sup>. On the occasions after 2-3 weeks when an increased concentration of colony forming units was found per cm<sup>3</sup> of blood, the marrow (and splenic red pulp) would classically show histological hyperplasia.

The results which followed a powerful antigenic stimulus were less expected. This stimulus is known to produce, in the peripheral blood of mice, cells capable of undergoing mitosis *in vitro* under the influence of phytohaemagglutinin (Breckon and Ford, unpublished). Observations indicate that histologically at the relevant time the bone marrow is hyperplastic and predominantly granulopoietic and with this is associated a granulocytic leucocytosis in the peripheral blood. The spleen is also hyperplastic: there is a brisk response to the antigen by the Malpighian bodies and the red pulp is hyperplastic and unduly myeloid, but mainly in the direction of erythropoiesis and megakaryocytopoiesis.

Micklem<sup>10</sup> has shown an increase of 30-100 per cent in CFU/cm<sup>3</sup> in the peripheral blood 3 days after intravenous injection of phytohaemagglutinin (0.3 ml.). This treatment entails a shock to the system (with leucopenia at this time) so severe that some of the mice died within 16 h.

The concentration of colony forming units in the blood is high in late foetal and early neonatal life<sup>9</sup>.

Previously<sup>11</sup> it was postulated that stem cells left the marrow and were transported by the blood to the thymus and perhaps other lymphatic tissue for committal to lymphoid successors. The possibly obligatory role of the thymus has now been excluded by examining thymectomized animals<sup>12</sup>. Micklem *et al.*<sup>13</sup>, however, could not decide whether the thymic precursors left the marrow as multipotent stem cells or as cells already committed to lymphoid development.

The stem cells have not yet been identified morphologically, despite claims that some small cells in the bone marrow are stem cells though similar looking cells in the lymph node and thymus are not<sup>14</sup>. Until stem cells are identified and marked, it will scarcely be possible to interpret whether increased concentrations in blood as reported here indicate an increased intake into or a decreased extraction from the blood stream. Nevertheless, for the moment it may be assumed that in the four cases cited here an increased intake is the more likely. In each case the time factors are such that there is an increased need for lymphoid cells. Restoration of the lymphoid tissues from damage by radiation is slow and succeeds regeneration of myeloid tissue while immune response demands an early hyperplasia of lymphoid tissue. Phytohaemagglutinin may have acted as an antigen or, as *in vitro*, as an immediate stimulant to lymphoid cells while the lymphatic tissue is emerging under the direction of the thymus<sup>15</sup>.

Because of the correlation so far between the concentration in blood of stem cells, identified as colony forming units, and the need for lymphocytes, we incline to the view that the lymphoid precursors leave the marrow as multipotent stem cells most of which find their way to lymphoid tissue where they are committed. Under the conditions of the present experiments these stem cells were taken from their primary hosts and installed in irradiated secondary hosts where there were other and more pressing requirements for granulocytes, platelets and later red corpuscles, so that the multipotent cells developed along these lines rather than to lymphocytes.

On this hypothesis we would predict that where there is a reduced demand for lymphocytes, as in the germ-free state, colony forming units should be in reduced concentration or absent from the peripheral blood, whereas if circulating lymphocyte precursors are committed cells their concentration might well be independent of that of colony forming units.

In summary, we found that colony forming units, present in normal circulating blood of mice in concentrations of about 10/cm<sup>3</sup>, were not detected after sub-lethal doses of X-rays (350 and 700 rads) until about 10 days later. Then they were present in normal, and in two instances increased, concentration. In other mice given a single immunizing injection of a mixture of pertussis vaccine and calf serum the concentration of colony forming units in blood was increased temporarily with a peak value of more than ten-fold after 7 days but returned to normal within 3 weeks. It is suggested from this and other observations that these colony forming units may be multipotent stem cells exported from myeloid tissue to colonize lymphoid tissue where they are committed to lymphoid differentiation.

## PHYSIOLOGY

### Dependence on Temperature of the Conduction Velocity of the Action Potential of the Squid Giant Axon

SEVERAL investigations of the effects of temperature on the squid giant axon have been made, but as yet the changes of the conduction velocity associated with altering the temperature have not been accurately determined<sup>1-3</sup>.

The conduction velocity of the action potential of the isolated giant axon has been measured over the temperature range -1° to +40° C. The action potentials were recorded by two glass microelectrodes filled with 3 molar potassium chloride (resistance 10-20 MΩ) inserted into the axon so that they were separated by 2 cm of

axon. Action potentials were evoked at 10/sec by brief currents applied through two silver wire electrodes at one end of the axon. The temperature was reduced by circulating pre-cooled sea water through the experimental chamber and measured by a small bulb mercury thermometer placed close to the axon. The sea water supply was then stopped and the conduction velocity and the temperature of the sea water were continually measured as the temperature gradually increased from  $-1^{\circ}$  or  $0^{\circ}$  C towards room temperature ( $25^{\circ}$  C). Adequate mixing of the sea water was achieved by vigorous aeration through the floor of the experimental chamber on either side of the axon. A similar procedure using sea water pre-warmed to  $40^{\circ}$  C was used to obtain temperatures above room temperature.

The distance between the two microelectrodes was measured with an eyepiece micrometer. The conduction time was measured from midpoint to midpoint of the rising phase of the action potentials.

Huxley<sup>4</sup> derived an expression for the conduction velocity based on a dimensional argument. It is

$$\theta^2 = \frac{a}{2R_2\gamma C_m} \varphi f(\eta/\varphi) \quad (1)$$

where  $\theta$  is the conduction velocity;  $a$  is the radius of the axon;  $C_m$  is the membrane capacity;  $R_2$  is the specific resistance of the axoplasm;  $\varphi$  is the factor by which the permeability changes are accelerated by a rise in temperature;  $\eta$  is the factor by which the absolute values of all the ionic currents are altered by temperature;  $\gamma$  is the factor by which the membrane capacity is changed by temperature.

The experimental and theoretical relations between conduction velocity and temperature are expressed for convenience as the logarithm of the change of the velocity relative to that at the standard temperature of  $6.3^{\circ}$  C (mean value  $9.15$  m/sec for the experimental velocity). The line (solid and dashed) in Fig. 1 has been computed by substituting  $Q_{10}$  values of 3.0 for  $\varphi$  (see ref. 5) and 1.3 for  $\frac{1}{R_2}$ , and a linear increase of 4 per cent/ $^{\circ}$ C of the  $15^{\circ}$  C value of  $\eta$  (see ref. 2), into the equation, and assuming that there was no change in the membrane capacity ( $\gamma = 1$ ) or the axon radius, and by obtaining the values for  $f(\eta/\varphi)$  from Fig. 20 in ref. 4, which is derived from the Hodgkin-Huxley equations. It is unlikely that  $\varphi$  and  $\eta$  can be reliably extrapolated beyond the range of temperature in which

Fig. 1. The effect of temperature on the conduction velocity (mean values) of ten squid giant axons (filled circles) and on the computed conduction velocity (solid and dashed line). In each case the velocity was taken as unity at the standard temperature of  $6.3^{\circ}$  C. The dashed lines represent the computed relative velocity in the temperature ranges where the predictions of the equation are likely to be unreliable (see text). The vertical bars represent  $\pm$  the standard deviation of the mean where this is larger than the filled circle.

they were originally determined ( $5^{\circ}$ – $25^{\circ}$  C); therefore the computed relationship of the conduction velocity at temperatures outside this range is shown as a broken line in Fig. 1.

Good agreement between the observed and the computed relationships is obtained in the temperature range where the predictions of the equation are probably most reliable, that is,  $5^{\circ}$ – $25^{\circ}$  C. At temperatures less than  $5^{\circ}$  C the conduction velocity shows a progressively greater dependence than predicted by equation (1). This divergence is presumably related to the striking increase in the thermal dependence of the duration of the action potential and of the threshold described by Spyropoulos<sup>3</sup> at temperatures near  $0^{\circ}$  C. In the giant axon of *Loligo vulgaris* the conduction of the action potential is reversibly blocked in the region of  $-0.5^{\circ}$  C; associated with the development of this cold block is a sudden reversible reduction of the resting potential by 15–30 mV. It may be, however, that the conduction block is not directly caused by this depolarization because action potentials can still be evoked under space clamp conditions<sup>4</sup>. At temperatures greater than  $25^{\circ}$  C the resting and action potentials are progressively reduced until conduction fails reversibly between  $35^{\circ}$  and  $37^{\circ}$  C, while the computed temperature for conduction failure is  $44.5^{\circ}$  C. Part of this discrepancy is related to the progressive reduction of the resting potential which occurs as the temperature is raised beyond  $25^{\circ}$  C, as these effects are not included in the equation.

The changes of the action potential with temperature, amplitude, maximum rate of rise and maximum rate of fall, were very similar to those reported by Hodgkin and Katz<sup>1</sup>, while the  $Q_{10}$  values for the conduction velocity were:  $0^{\circ}$ – $10^{\circ}$  C, 2.21 s.d. 0.27;  $10^{\circ}$ – $20^{\circ}$  C, 1.70 s.d. 0.03;  $20^{\circ}$ – $30^{\circ}$  C, 1.40 s.d. 0.01; which are close to those reported for other nerve fibres.

I thank Prof. A. F. Huxley for help and guidance with the computations, and I acknowledge the provision of animals and equipment by the Stazione Zoologica, Naples, and the financial support of the Nuffield Foundation.

### Responses of Muscle Spindles in the Lizard

In the past 30 years many experiments have been carried out on the structure and function of muscle spindles in both amphibia and mammals. There have been no accounts of experiments concerned with the function of muscle spindles in reptiles although their structure has been described<sup>1,2</sup>.

The muscle spindles of both snakes and lizards usually contain a single intrafusal muscle fibre. A large afferent nerve fibre enters the central capsular region of the spindle, and then bifurcates with each of the two branches running in opposite directions along the surface of the muscle fibre. Spindles commonly occur in a tandem arrangement<sup>3</sup>, with motor endings between the adjacent sensory regions. In lizards the intrafusal muscle fibres are innervated by branches of motor fibres that also supply extrafusal muscle fibres<sup>1</sup>. The number of motor endings on the spindle varies, but most commonly one occurs near each pole of its capsule.

All the anatomical and physiological findings presented here were made with the pubotibialis muscle of the southern blue tongue lizard *Tiliqua nigrolutea*. The nerve supply to this muscle was isolated and the severed end of the sciatic nerve was split into fine filaments from which

responses were recorded. Changes in tension produced in the muscle were recorded by a tension transducer attached to the tendon of the muscle.

In fifteen experiments a total of sixty-five units was examined. Forty-seven units were randomly selected and, of these, thirty-two showed a resting discharge with the muscle slack while the other fifteen were silent unless some tension was applied. The frequency of the resting discharge varied between 3 and 20/sec, with the maximum discharge rate of 180–300/sec. At appropriate stimulus strengths all units showed "in parallel" behaviour, that is, the discharge was interrupted during the rising phase of the contraction and accelerated during the falling phase. The low mechanical threshold and "in parallel" behaviour were the criteria used to classify these responses as coming from muscle spindles<sup>4</sup>. At a critical stimulus strength, bursts of afferent discharge appeared in all or nothing fashion during the phase of increasing tension. Such an apparent "in series" response occurred for all the units examined. No responses of a "tendon organ" pattern were ever observed, that is, where the response discharge increases with increasing twitch tensions. By contrast the discharge of all the above units was reduced in intensity as larger portions of the muscle contracted. Fig. 1 illustrates some typical responses; the upper traces represent the afferent discharge while the lower trace is a recording of the tension changes in the muscle. *A* represents the resting discharge with no tension on the muscle. A weak shock to the muscle (*B*) results in a small contraction which interrupts the afferent discharge during the rising phase of the contraction and accelerates the response during the falling phase. In *C* the stimulus strength to the muscle has been only slightly increased, but this has brought in a burst of action potentials during the rise of tension. This

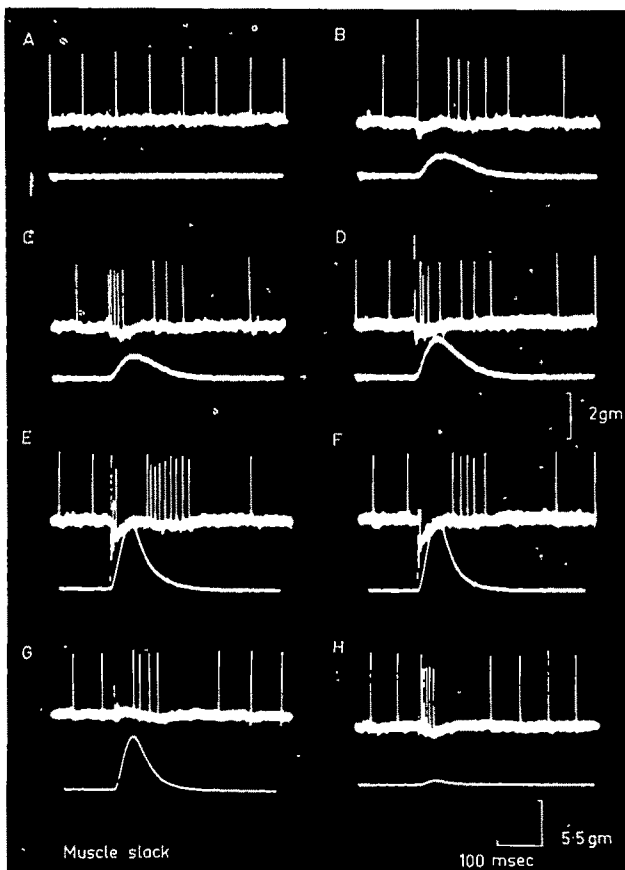

Fig. 1. Stretch receptor discharges from the pubotibialis muscle recorded from fine filaments of the dissected sciatic nerve. The upper trace in each record represents the nerve discharge while tension is recorded on the lower trace. For explanation see text.

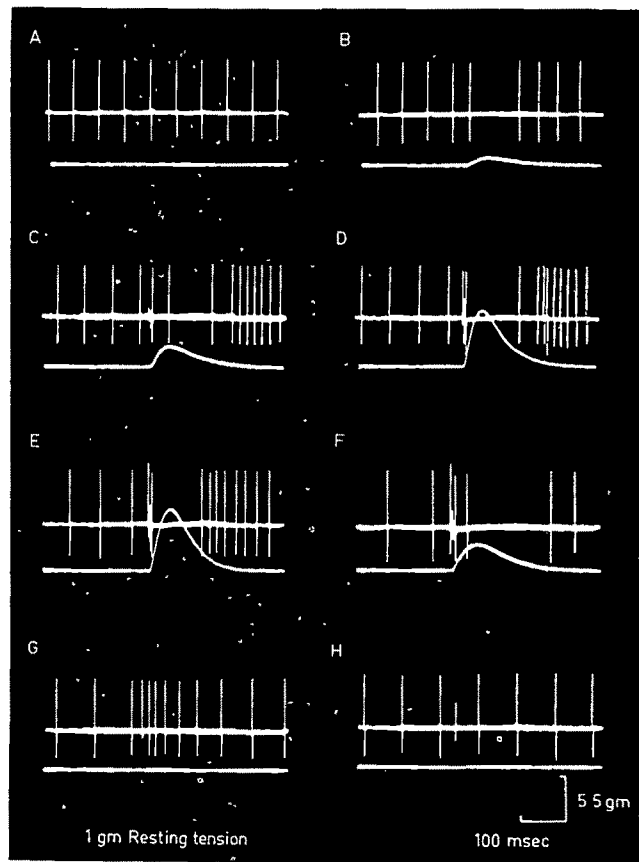

Fig. 2. Stretch receptor discharges from the pubotibialis muscle at a resting tension of 1 g. For explanation see text.

burst is reduced for higher twitch tensions (*D* and *E*) while in *F*, using a supramaximal shock, it completely disappears. With a greater resting tension of the muscle, the number and frequency of the "in series" discharges increased and were no longer completely removed at maximal twitch tensions.

A spike discharge on the rising phase of the contraction can be attributed to stray extrafusal muscle fibre pulls acting on the spindle<sup>6</sup>. If the motor supply to the muscle is reduced so that only single motor units are stimulated, then the possible effect of stray pulls will be minimized. This technique has been applied to the muscle of lizards. While recording from one filament the rest of the nerve was split and small filaments stimulated. Stimulation of the majority of filaments did not alter the afferent discharge. A few filaments caused the unit to behave in an "in parallel" fashion (Fig. 1*G*) while one or occasionally two filaments (which appeared to behave as single motor units) resulted in a powerful burst discharge on the rising phase of the contraction (Fig. 1*H*). The specificity of this response to the minimal motor stimulus makes it unlikely that it results from extrafusal stray pulls.

In the frog the intrafusal motor endings are less sensitive to curare than extrafusal endings<sup>8</sup>. This enables extrafusal contractions to be blocked without affecting intrafusal junctions: this differential neuromuscular block was also achieved in lizards using the drug 'Flaxedil' (gallamine triethiodide). Fig. 2 *A-D* shows responses from another unit. Here the discharge on the rising phase of the twitch consists of two spikes which are reduced to one at higher twitch tensions. 'Flaxedil' (2 mg) was then introduced intravenously. Fig. 2 *E-H* shows that as the twitch size gets smaller, the discharge on the rising phase of the contraction is unmasked, and persists even though there is no tension being registered. If the responses on the rising phase of the contraction were caused either by stray

extrafusal pulls or by ephaptic stimulation from extrafusal muscle action potentials then they would have been expected to disappear on application of the extrafusal neuromuscular block. The persistence of this response can be taken as positive evidence that it arises from a specific intrafusal contraction.

From these findings, it is suggested that large motor axons branch to supply both intrafusal and extrafusal muscle fibres. This was confirmed by examination of a number of histological preparations and appears to be a common feature. Whether this pattern of innervation occurs exclusively or whether occasionally the intrafusal fibre is innervated by unbranched motor axons is difficult to determine, but histological observations suggest that the latter occur rarely. The apparent absence of a specific motor supply to the lizard muscle spindle distinguishes this group from mammals and relates it to the amphibians, although the reptilian receptor is unique in the simplicity of its construction. The functional significance of the differences in structure remains as yet unknown.

I thank Professor A. K. McIntyre for criticism and encouragement.

### Release of Factor VIII (Antihæmophilic Factor) from Perfused Organs and Tissues

It has been known for many years that patients with classic hæmophilia bleed because they lack a plasma factor required for normal blood coagulation. This factor, factor VIII (antihæmophilic factor) of normal plasma, has been extensively investigated, but its exact site of origin is unknown. Recent developments in organ transplantation have stimulated us to look for the specific organ source of this procogulant. If the site of synthesis of factor VIII could be identified, permanent replacement of the deficient factor in hæmophilia might be possible. In the past, a variety of experimental approaches has been used to investigate the body's mechanisms for maintaining hæmostatic levels of factor VIII: organ ablation<sup>1</sup>, total body irradiation<sup>2</sup>, administration of hepatotoxins<sup>3,4</sup>, reticulo-endothelial blockade<sup>5</sup>, physical exercise<sup>6</sup>, hormone administration<sup>7</sup>, and thromboplastin injections<sup>8</sup>. Several recent investigations have suggested that the spleen may play a part in the regulation of concentrations of factor VIII in the plasma of normal individuals. Weaver *et al.* demonstrated that factor VIII is maintained at normal concentrations when intact normal dogs are cross-circulated with hæmophilic dogs, but that the concentrations decrease if a splenectomy is first performed on the normal animals<sup>9</sup>. In humans, Libre *et al.*<sup>10</sup> have observed that splenectomy abolishes the rise in factor VIII that is known to follow injection of adrenaline into normal subjects<sup>10</sup>. Pool was able to recover antihæmophilic activity in extracts of splenic tissue, but not from a variety of other tissues<sup>11</sup>.

The availability of both hæmophilic and normal dogs for experimental use has made it possible for us to explore the problem of factor VIII production by perfusing isolated organs with hæmophilic blood. A systematic investigation of major organs has now added direct evidence that the spleen is one of the sources of factor VIII and that, therefore, it may play an important part in

maintaining physiological plasma concentrations of this factor. Some of these perfusion experiments are reported.

Organs and tissues to be perfused were obtained from normal mongrel dogs or from dogs hemizygous or heterozygous for classic hæmophilia<sup>12</sup>. The dogs weighed about 20 kg. The animals were anaesthetized with sodium pentobarbital, and major vessels of the part to be perfused were isolated and cannulated with vinyl plastic tubing. Prompt irrigation with citrated saline (4° C) was started and was continued during and after excision of the organ; removal of retained blood usually required about 4–6 l. of citrated saline. Perfusion was then performed by recycling citrated hæmophilic whole blood (37° C) through the organ. The blood was propelled by a 'Sigma' motor pump and was oxygenated in a paediatric aerator at an oxygen flow rate of 1–2 l./min. Blood samples were withdrawn at intervals, centrifuged and the plasma stored at –20° C until assayed for factor VIII activity<sup>13</sup>.

Sample data are presented in Table 1. In each experiment, no factor VIII could be detected in the effluent at the conclusion of saline irrigation and at the time whole blood perfusion was begun. There was then a lag period of at least 30 min before appreciable factor VIII activity appeared, and then no activity could be obtained from normal lung or kidney or from a hæmophilic spleen. High concentrations of antihæmophilic activity consistently appeared only with perfusion of normal and heterozygous spleens. At periods later than those tabulated, values as high as 110 per cent were obtained. Less activity was recovered from an isolated hind limb and from the liver of normal dogs.

All the organs selected from these perfusion investigations were highly vascular structures. Thus, the possibility of blood being sequestered within closed areas of the microcirculation must be considered. Relatively complete removal of blood seems to have been accomplished, however, for we failed to detect any activity of factor VIII after irrigation with saline. In one experiment, an additional attempt to exhaust the spleen of pooled blood was made by repeated injections of adrenaline chloride into the irrigation medium. This resulted in splenic contraction and expression of additional blood, but did not prevent the later increase in factor VIII concentrations. Further, in another experiment, saturation of a hæmophilic spleen with normal blood was first accomplished by cross-circulation of a hæmophilic dog with a normal dog for 60 min. The accumulated factor VIII was easily exhausted from the isolated spleen by irrigation and no further factor VIII appeared on perfusion, even when adrenaline was introduced. Furthermore, the kidney and lung are also highly vascular viscera and offer opportunity for pooling of blood in the microcirculation. These organs, however, failed to yield detectable factor VIII when they were perfused. It is of interest that the isolated kidney is not inert in similar circumstances; it will release plasminogen activator when perfused and stimulated with vasoactive drugs<sup>14</sup>.

A second common structural denominator between the organs in which activity of factor VIII was found is that each is relatively rich in reticulo-endothelial elements. It is therefore interesting to recall the experiments that Pool and Spaet performed 13 years ago that tended to point to the reticulo-endothelial cells as the site of factor VIII

Table 1. RELEASE OF FACTOR VIII WITH PERFUSION

Organ perfused	No. of experiments	Mean factor VIII after 90 min*	Range*
Normal hind limb	4	3.4	<1–9
Normal liver	1	9.5	—
Normal lung	2	<1	<1
Normal kidney	3	<1	<1
Normal spleen	7	49	27–65
Hæmophilic spleen	1	<1	—
Heterozygous spleen	1	43	—

\* Values are expressed as percentage of activity of a normal canine plasma control.

production<sup>17</sup>. Penick *et al.* were able to depress partially the levels of circulating factor VIII by damaging the liver with chloroform<sup>4</sup>. More recently, Straub *et al.* have shown that factor VIII concentrations can be elevated in the presence of lethal liver necrosis<sup>15</sup>. In earlier experiments<sup>2</sup>, destruction of much of the splenic parenchyma by total body irradiation had failed to depress factor VIII, but the reticular cells in these animals appeared to be viable histologically. Although lung macrophages are often included as a component of the reticulo-endothelial system, the lung does not appear to release significant amounts of factor VIII.

It was initially feared that thromboplastin might be released from blood cells during the extracorporeal circulation and masquerade as factor VIII. No factor VIII activity was detected, however, in the perfusates from the lung, kidney and the haemophilic spleen, even though appreciable haemolysis was evident during the terminal stages of each experiment. Neither did the perfusate shorten the recalcification time of platelet-free normal plasma. In fact, it may be that the detected concentrations of factor VIII were erroneously small, for it has been shown that extracorporeal circulation and aeration of blood can cause some consumption of factor VIII (ref. 16).

Organ perfusion appears to offer positive and direct evidence that organs containing reticulo-endothelial elements, and especially the spleen, are capable of releasing factor VIII into the circulation. In all experiments so far, it is difficult to decide whether the role of the spleen is one of storage or production. Furthermore, it is well established that asplenic humans and animals do not develop a permanent deficiency of factor VIII (refs. 8 and 9). Thus, it is especially interesting that we were able to demonstrate some factor VIII in perfusates from the liver and leg. It is conceivable that the liver and bone marrow could be able to compensate for a removed spleen in its role of releasing factor VIII.

This investigation was supported in part by grants from the U.S. Public Health Service.

## Antagonism of Intra-arterial Acetylcholine Induced Contraction of Skeletal Muscle by Sea Snake Venom

Marsden and Reid<sup>1</sup> in their investigations on victims of sea snake (*Enhydryna schistosa* Daudin) poisoning found evidence of progressive muscular weakness and myonecrosis. Carey and Wright<sup>2</sup>, however, concluded that the venom had a neuromuscular blocking action when tested on the isolated rat phrenic nerve-diaphragm preparation.

Fig. 1. Comparison of height of muscle contraction caused by indirect stimulation of anterior tibial nerve (●—●) and that caused by intra-arterial acetylcholine (○—○) after *E. schistosa* venom in a cat weighing 2.0 kg.

Our investigations of the pharmacological properties of the venom confirmed the development of muscle weakness and respiratory paralysis in the intact guinea-pig, although in animals which acutely succumbed to subcutaneous injection of the venom there was no histological evidence of muscle necrosis. Evidence obtained from the isolated phrenic nerve diaphragm and sciatic nerve gastrocnemius preparation of the rat suggested a neuromuscular blocking action.

In the cat tibialis anterior muscle preparation, however, it was possible to demonstrate repeatedly that small doses of venom could abolish twitches caused by intra-arterial acetylcholine without interfering with muscle contraction resulting from a supramaximal electrical stimulus applied to the anterior tibial nerve<sup>3</sup>. Neither was the post-tetanic facilitation modified. Only with comparatively large doses was there gradual and progressive diminution in neuromuscular transmission (Fig. 1).

This abolition of muscular twitch from intra-arterial acetylcholine without any apparent change in neuromuscular transmission is contrary to traditional concepts of acetylcholine as the transmitter substance at the neuromuscular junction<sup>4</sup>. Furthermore, we have been unable to detect any atropine-like or cholinesterase activity in the venom. It is difficult to reconcile this interesting finding without postulating that acetylcholine may not be the actual substance affecting the sub-neural membrane of the motor endplate as the transmitter substance. There is evidence<sup>5</sup> which suggests that acetylcholine may act on the motor nerve terminal to trigger off an unknown mechanism for muscle contraction<sup>6</sup>. Iontophoresis<sup>7</sup>, though fine enough to localize acetylcholine action to the motor endplate region, is, nevertheless, unable to discriminate between the different components of the motor endplate thus affected. The action of sea snake venom can apparently differentiate between cholinceptive sites which cause the muscle twitch from acetylcholine and the receptor sites responsible for contraction of indirectly stimulated muscle.

The exact location of acetylcholine action is difficult to resolve. There is evidence for action at the motor nerve terminal<sup>5</sup> and a possibility of action on receptors on the muscle membrane outside the motor endplate region<sup>8,9</sup>. Either or both could account for our observation, but we feel the former is a more likely explanation because the latter has been shown to be a phenomenon peculiar to chronic denervation.

## GENETICS

### Presence of the Duffy Blood Group Gene *Fy<sup>b</sup>* demonstrated in Melanesians

THE Duffy (*Fy*) blood group discovered in 1950 was the eighth of the principal blood group systems to be identified. The first antigen found was called *Fy<sup>a</sup>* and its corresponding antibody anti-*Fy<sup>a</sup>*. The antithetical antigen *Fy<sup>b</sup>* and its antibody anti-*Fy<sup>b</sup>* was found in 1951. These antibodies occur as natural antibodies or as the result of immunization by blood transfusion or by pregnancy, and it is known that anti-*Fy<sup>a</sup>* may cause haemolytic blood transfusion reactions and also haemolytic disease of the newborn. Two alleles, however, *Fy<sup>a</sup>* and *Fy<sup>b</sup>*, have not been sufficient to explain the Duffy reactions found in inheritance, and a third allele, *Fy*, occurring frequently in Negroes and occasionally in Caucasians, has been postulated although no anti-*Fy* antibody has been found. The distribution of both *Fy<sup>a</sup>* and *Fy<sup>b</sup>* in Caucasians and in Negroes has been thoroughly investigated, while Japanese and Koreans tested with only anti-*Fy<sup>a</sup>* have been found to be almost 100 per cent anti-*Fy<sup>a</sup>* positive<sup>10</sup>. During 1953-61 blood group research workers published findings on the distribution of the Duffy *Fy<sup>a</sup>* blood group gene in the Pacific peoples, and these investigations have shown that, with the exception of the Polynesians<sup>1</sup>, other Pacific peoples including Melanesians are, with few exceptions, 100 per cent *Fy(a+)*, that is, all blood samples tested have reacted with anti-*Fy<sup>a</sup>* testing reagent.

The present communication deals exclusively with investigations carried out on various groups of people within the Melanesian population during 1965, and the new data presented demonstrate that the Duffy *Fy<sup>b</sup>* gene is also present in Melanesians, but its distribution is limited to certain linguistic groups living in different geographical locations.

The recent investigations were made possible by the identification in Melbourne in 1964 of a potent saline agglutinating anti-*Fy<sup>a</sup>* antiserum by one of us (R. T. S.), and as a result many blood grouping laboratories in different countries have received this serum for special work. Only a few examples of anti-*Fy<sup>b</sup>* antisera have been found since its discovery<sup>2</sup>, and at no time have supplies of this important testing reagent been available for extensive investigations in racial blood group genetics. Table 1 summarizes the results of anti-*Fy<sup>a</sup>* testing recorded in the years 1953-61 for various linguistic groups in the

Melanesian populations of New Britain, Papua-New Guinea, West New Guinea and the Solomon Islands (B.S.I.P.). In all, 2,392 blood samples out of 2,397 (99.8 per cent) were found to be *Fy(a+)*. In New Britain all of the 132 samples from five linguistic groups (100 per cent) were all *Fy(a+)*, in New Guinea 1,410 out of 1,411 (99.9 per cent) were *Fy(a+)*, in West New Guinea 712 out of 715 (99.6 per cent) were *Fy(a+)* and in the Solomon Islands 138 out of 139 (99.3 per cent) were *Fy(a+)*. It was uncertain whether the one negative recorded in New Guinea, the three negatives in West New Guinea and the one negative found in the Solomon Islands were truly negative, or whether they had failed to react because of technical difficulties, or because of the age of the blood samples when tested. It seemed reasonable to conclude that the latter was possibly the case in samples from West New Guinea which were 6-9 months old when tested, after storage at 5° C in glucose-citrate solution. Thus, the unanswered question was whether the *Fy<sup>a</sup>* frequency in Melanesians was 100 per cent, or whether there was another Duffy gene also present to explain the five negatives recorded in the 2,397 tests made.

Investigations carried out in 1965 with both anti-*Fy<sup>a</sup>* and anti-*Fy<sup>b</sup>* saline agglutinating sera versus 20 per cent red cell suspensions in glucose-citrate solution<sup>18</sup> on slides kept in moist-chambers, and read after 60 min at 22° C, gave the results of Table 2. The anti-*Fy<sup>a</sup>* agglutinating serum has been in use in Melbourne since its identification in 1957.

Throughout the year samples were flown to Melbourne for blood group genetic investigations from New Guinea, from Manus Island in the Admiralty Islands, the Solomon Islands, the New Hebrides and, in December 1965, from New Britain. In all, 892 out of 892 (100 per cent) of the New Guinea samples were *Fy(a+b-)*, 124 out of 124 (100 per cent) of the Manus Island samples were *Fy(a+b-)*, and 142 out of 142 (100 per cent) of the New Hebrides samples were *Fy(a+b-)*. In tests on the forty-seven Guadalcanal (Solomon Islands) samples, forty-six were *Fy(a+b-)* and one was *Fy(a+b+)*. Previously (Table 1) one sample in 139 from Guadalcanal was *Fy(a-)*. It was in New Britain, however, that tests on peoples of the Tolai and Sulka linguistic groups

Table 1. SUMMARY OF DUFFY *Fy<sup>a</sup>* INVESTIGATIONS IN MELANESIANS, 1953-1961

Population	Location or administrative district	Linguistic group	Proportion <i>Fy(a+)</i>	Percentage <i>Fy(a+)</i>

\* Locations of linguistic groups in New Britain have been presented by Simmons *et al.*<sup>2</sup> in 1964.

† The Administrative Districts of New Guinea have been presented by Simmons *et al.*<sup>11</sup> in 1961.

‡ The blood samples were 6-9 months old when tested with anti-*Fy<sup>a</sup>* serum.

Table 2. DUFFY  $Fy^a$  AND  $Fy^b$  BLOOD GROUP GENES AS FOUND IN MELANESIANS IN 1965

Population	Location or administrative district	Linguistic group	No. tested	$Fy(a+b-)$	Duffy blood types $Fy(a+b+)$	$Fy(a-b+)$
New Britain	Gazelle Peninsula	Tolai	100	88	11	1
		Sulka	36	32	4	0
Total			136*	120	15	1
Admiralty Islands	Manus Island	Several	124	124	0	0
New Guinea	Sepik District	Several	260	260	0	0
	Eastern Highlands	Several	338	338	0	0
	Eastern Highlands (kuru patients)	Fore	35	35	0	0
Total	Morobe District	Kukukuku	259	259	0	0
			892	892	0	0
Solomon Islands	Guadalcanal	.	47	46	1	0
New Hebrides	Emai Island	.	95	95	0	0
	Emau Island	.	47	47	0	0
Total			142	142	0	0
Grand total			1,341	1,324	16	1

\* The gene frequencies for 100 random Tolai were:  $Fy^a$  0.9360  $Fy^b$  0.0650  
and for 36 random Sulka were: 0.944 0.056

revealed the presence of an unsuspected frequency of the  $Fy^b$  gene. In a total of 136 random samples tested out of 457 blood samples received, we found 120 out of 136 (88.2 per cent)  $Fy(a+b-)$ , fifteen (11.0 per cent)  $Fy(a+b+)$  and one (0.7 per cent)  $Fy(a-b+)$ . Thus, two linguistic groups in New Britain have been proved to possess the blood group gene  $Fy^b$  as well as  $Fy^a$  and this also applies to a small sampling from the Solomon Islands.

The inheritance of both  $Fy^a$  and  $Fy^b$  genes in a number of Tolai and Sulka families was checked with no evidence of any atypical inheritance, or the presence of a third Duffy gene being indicated. The results of these family investigations form part of a series of blood group genetic investigations, the results of which will be presented elsewhere.

## BIOLOGY

### *Macrostomum tuba* (Graff), 1882 (Turbellaria, Rhabdocoela), recorded in British Freshwater Aquaria

THE macrostomid rhabdocoel *Macrostomum tuba* has its main distribution in central and southern Europe and Japan, and appears to be absent from northern Eurasia<sup>1,2</sup>. It has been found, however, in a few warmed aquaria and warmed pools in botanical gardens in the latter region for example, Stockholm, Berlin, Munich, Warsaw and Helsinki, and also in New York.

The species has been present in considerable numbers in a few warmed aquaria (21° C) at the I. M. Marsh College of Physical Education, Liverpool, since January 1966. There is every reason to believe that it will persist here, because Luther<sup>3</sup> comments that the species has lived in warmed aquaria in Helsinki for many years. The source of the rhabdocoels was traced to a shop called "The Liverpool Aquaria" which supplies the College with biological material, and an examination of their warmed aquaria revealed one specimen; the paucity of animals is not surprising, because the tanks are cleaned at frequent,

Fig. 1. *A*, *Macrostomum tuba*, a mature example of 2 mm length ( $\times 54$ ). *B*, Male copulatory apparatus of same ( $\times 120$ ). *C*, Penis stylet (varied from 280 to 420  $\mu$  in sixteen specimens examined). 1, Eye; 2, mouth; 3, pharynx; 4, testes; 5, intestine; 6, ovary; 7, female atrium; 8, male copulatory apparatus; 9, vesicula granulorum (prostatic vesicle); 10, vesicula seminalis; 11, vas deferens; 12, false seminal vesicle (spermiducal vesicle); 13, penis stylet; and 14, bulb-shaped distal tip.

regular intervals. It is probable that the living rhabdocoels, or a resistant phase, were unintentionally imported into Britain with animal or plant consignments from one of the regions, namely North and South America, Singapore, India, Holland and East Germany, which supply the importers. Thus, the animal may be present in other warmed aquaria in Merseyside and indeed could be widespread in aquaria in Britain. In view of the recent introduction of the American freshwater triclad *Dugesia tigrina* (Girard) to Britain, probably through the activities of aquarists<sup>3,4</sup>, and its subsequent spread into natural habitats, the authors advocate that similar introductions should be put on record. It is pertinent to mention that an extensive sampling programme for rhabdocoels in diverse freshwater habitats in Merseyside has not yielded any *M. tuba* as yet.

The anatomy of *M. tuba* has been described adequately<sup>5-7</sup> but Fig. 1, drawn from the animals found in Liverpool, has been included to aid the easy identification of mature animals. These specimens apparently conform with the widely spread form of the species which has a long stylet with a relatively small vesicula granulorum; the short styleted form with larger vesicula granulorum appears to be limited to Germany<sup>8</sup>.

### Effect of Amino-acids on the Transport of Bovine Immune Lactoglobulin across New-born Pig Intestine

THE everted small intestine of the newborn pig, formed into sacs and incubated in a preparation of dialysed bovine colostrum, transports bovine immune lactoglobulin to the serosal surface; most of the protein transport occurs across sacs made from the middle third of the intestine<sup>1</sup>. This part of the small intestine is not outstanding in its ability to transport either water, sodium or glucose, but in other mammals this is the area for maximal transport of several amino-acids<sup>2</sup>. Amino-acids can either induce or suppress endocytosis in amoebae<sup>3</sup> and it was these two observations which suggested that amino-acids could influence protein transport in the pig intestine.

Akedo and Christensen<sup>4</sup> have shown that certain amino-acids cross mucosal cell membranes mainly by facilitated diffusion while others make use of an active transport mechanism. In the present investigation, L-leucine and L-alanine were chosen to represent amino-acids crossing by these two processes respectively. L-Methionine was also used; it is thought to cross cell membranes by both mechanisms<sup>5</sup> and is known to inhibit the intestinal transport of other amino-acids<sup>6</sup>.

Piglets, removed from the sow immediately after birth, were used within 2 h of birth. The induction of anaesthesia, dissection of intestine and preparation of everted sacs have been described in detail elsewhere<sup>1</sup>. The whole of the small intestine was divided into ten segments of equal length and segments 6 and 7 were removed for the following experiments. Everted sacs, formed from these two segments, six sacs in all, were partly filled with 0.3 ml. of bicarbonate saline<sup>7</sup> and incubated in bovine colostrum,

dialysed previously against bicarbonate saline. An amino-acid was sometimes added to the bovine colostrum after dialysis in a concentration of 10 mmol/l. Incubation was for 2 h at 37°C in a medium gassed with 95 per cent oxygen + 5 per cent carbon dioxide. A smear of silicone antifoam emulsion around the top of each tube controlled frothing produced by gassing. The dialysed bovine colostrum contained 138 mmol/l. of sodium; 6.7 mmol/l. of potassium; 25 mmol/l. of glucose; total protein 10.4 per cent (w/v); (immune lactoglobulin 6.3 per cent w/v). The pH of this solution when equilibrated with the mixture of oxygen and carbon dioxide was 7.4. Transmural potentials were recorded during incubation and fluid transfer calculated at the end of incubation<sup>1</sup>. At the end of incubation the serosal fluids were analysed for glucose by the method of Hansen<sup>8</sup> and for bovine immune lactoglobulin by the quantitative immunodiffusion test of Geil<sup>9</sup>. Serosal transfers were calculated as µg of bovine immune lactoglobulin, or ml. of fluid, or mg of glucose appearing/g of intestine/h of incubation. Serosal transfers were determined across sacs incubated in colostrum containing the amino-acid which was being tested and alternate sacs served as controls. The significance of differences was assessed using the Wilcoxon test<sup>10</sup>.

The mean control serosal transfers, determined on forty-eight sacs, were: bovine immune lactoglobulin, 61.6 µg/g/h; fluid, 0.5 ml./g/h; glucose, 1.9 mg/g/h. The mean transmural potential was 4.4 mV. Changes from these control values, measured in the presence of different amino-acids, are shown in Fig. 1. L-Alanine did not significantly change any of the parameters measured. L-Leucine inhibited protein transport, but it was impossible to say whether this was a direct effect or only secondary to the inhibition of water and glucose transport which occurred when this amino-acid was present. L-Methionine inhibited protein transport without changing the transmural potential or the serosal transfer of fluid or glucose. None of these effects were seen when the D-isomers were used (see Fig. 2).

The specificity of L-methionine as an inhibitor of protein transport implies a direct action on some part of the protein transferring mechanism; the absence of any effect using the D-isomer of methionine eliminates the possibility that the inhibitory action is dependent on the electrical charge carried by the molecule at pH 7.4. We have already suggested that different protein molecules show different specificities for binding sites at the luminal border of the mucosal cell and that selectivity in absorp-

Fig. 1. Effect of L-amino-acids on the transmural potential and serosal transfers of bovine immune lactoglobulin, fluid and glucose, measured across the everted small intestine of the newborn pig. Everted sacs were incubated in dialysed bovine colostrum for 2 h at 37°C. The initial concentration of amino-acid in the mucosal fluid was 10 mmol/l. Comparisons were made with alternate sacs incubated in colostrum containing no added amino-acid. Each histogram gives the mean change from comparisons. Open histograms, no significant change; cross-hatched histograms, change significant at the level of probability *P* shown in the figure.

Fig. 2. Comparison of control transmural potentials and serosal transfers of bovine immune lactoglobulin, fluid and glucose, across the everted pig small intestine, with those found in the presence of D-amino-acids. Conditions of incubation were the same as in Fig. 1. Histograms give the mean change from six comparisons. None of the changes were statistically significant.

tion could occur before endocytosis takes place<sup>1</sup>. This would be analogous to the process of endocytosis of protein in amoebae<sup>2</sup>. If methionine and leucine, but not alanine, were to compete with bovine immune lactoglobulin for a common receptor at the mucosal membrane, this would explain the inhibitory action of these amino-acids and suggest that the postulated receptor is one normally responsible for the facilitated diffusion of amino-acids into the mucosa. The possibility that protein could be transported across intestines at a rate which depends on an affinity for a mechanism of facilitated diffusion was first suggested by Danielli in 1954 (ref. 11).

This idea can now be tested in greater detail using other amino-acids with known affinities for a facilitated diffusion mechanism, in the hope of finding some which inhibit protein transfer without changing fluid movements.

We thank Mr. M. Rennie and Mr. K. Burton for technical assistance.

### *Gwynia capsula* (Jeffreys), an Articulate Brachiopod with Brood Protection

THE articulate brachiopod *Gwynia capsula* (Fig. 1), which is only about 1 mm in diameter, was described by Jeffreys in 1859 and recorded during the last half of the nineteenth century from several marine localities in Great Britain, as well as from the continental side of the Channel. Because of the very small size of the animal, it was suggested that it might be the juvenile stage of some larger known species<sup>1</sup>. In spite of older records<sup>1,2</sup> the species is not listed in the *Plymouth Marine Fauna*<sup>3</sup> and it is quoted as a doubtful species in modern text-books<sup>4,5</sup>.

According to the description<sup>6,7</sup>, *Gwynia capsula* has some morphological details which are interesting from the point of view of brachiopod phylogeny. One of these features is the lophophore, which represents the simplest (trocholophous) type. A revision of the morphology of *Gwynia capsula* is now in progress in this laboratory.

I found *Gwynia capsula* living in sub-tidal sand at Church Island, near the Marine Science Laboratories, Menai Bridge, in 1956. It was found there again in 1964 and 1965. The particular sediment of the locality is a mineral sand containing a high portion of fine broken shell. The population seems scarce and the individuals were found one by one sheltered in tiny fragments of serpulid tubes. Others previously found *Gwynia capsula* fixed to the undersides of stones in the sub-tidal region. The findings at Menai Bridge indicate that the species can also be included in the rare category of sedentary animals of the interstitial fauna of marine sand<sup>8</sup>. Live specimens have been kept in the laboratory for

Fig. 1. *Gwynia capsula* (Jeffreys), two specimens living inside a fragment of a serpulid shell.

Fig. 2. *Gwynia capsula* (Jeffreys), larva from brood pouch of female.

considerable periods. Animals caught at Church Island in October 1964 were still alive at Kristineberg in August 1965, although no food had been added. It is believed, therefore, that *Gwynia capsula* feeds on micro-organisms.

If *Gwynia capsula* is interesting from a morphological point of view, it is also certain that it has a peculiar type of reproductive biology. Like many organisms of very small body size<sup>8</sup>, *Gwynia capsula* produces only a limited number of gametes. In the female gonad the eggs develop in the body cavity of the mother animal in a kind of brood pouch, at least up to the stage where three segments have been formed (Fig. 2). Only two embryos develop at one time. Biologically, brood protection has been considered to be an adaptation which favours the maintenance of populations of species producing low numbers of gametes<sup>9</sup>.

It is concluded, from the foregoing observations of reproduction at Bangor, that *Gwynia capsula* (Jeffreys) is a distinct species, which reaches the adult stage at a body size of only about 1 mm. It is the smallest articulate brachiopod known so far.

### Blood Concentrations of Caesium-137 in People in the Far East and the Pacific Region

CAESIUM-137, a fission product with a long half-life, is liable to be transmitted through the food chain to man when the environment is contaminated by radioactive fall-out. From the behaviour of caesium-137 concentrations in humans observed in several countries since 1959, it has been suggested that the concentrations in people vary with the current rates of fall-out and the cumulative concentrations in the environment as well as the food habits. Special emphasis should be laid on the last factor, because in some groups of Scandinavian Laplanders and Alaskan Eskimos average body burden in 1961 reached concentrations forty to sixty times greater than the average for northern temperate regions. The enhanced concentrations are believed to depend on particular food chain mechanisms comprising high consumption of highly contaminated meat of caribou or reindeer<sup>1</sup>.

Measured values of caesium-137 in humans have been reported from about a dozen countries representing altogether a population of 500 million, but this is only a small fraction of the world population of 3,200 million and data for people living in Asia and the southern hemisphere are very scant. Measurements of the total body burden of caesium-137 have been made conveniently with whole body counters. A world survey of whole body monitors revealed that 67 per cent of the apparatuses were used to measure caesium-137 in the general public, but in fact the main use of these apparatuses is for occupational groups and patients<sup>2</sup>. Although mobile counters are available and used in the survey of Laplanders and Eskimos, the world distribution of the apparatuses is too uneven to give worldwide information about the concentrations of caesium-137 in the populace.

A method of blood analysis was proposed by Yamagata<sup>3</sup> as a promising substitute for whole body counting in countries where rather expensive counters are not available or limited in use for the general public. This method

makes use of the citrated whole blood which can be made available through blood bank or blood transfusion systems. A minimum quantity of about 100 ml. of blood is required currently for radiochemical determination of caesium-137 (ref. 4) and the amount of added anticoagulant has to be known for correction purposes. Measurement of activity is made by a low-background counting system in order to measure  $\beta$ -activity as low as a few d.p.m.

For the estimation of total body burden, the factor relating the concentration of caesium-137 in blood to the total body burden must be known. To obtain such a factor, the blood analysis and whole body counting were conducted monthly for a number of laboratory personnel between June and December 1964, when a stationary state was likely to exist in the body burden, indicating a quasi-equilibrium condition between the diet and body<sup>5</sup>. The factor relating the concentration of caesium-137 in blood to the total body burden as expressed in the formula

$$f = \frac{\text{Total body burden of caesium-137 (pc.)}}{\text{Body weight (kg)} \times \text{caesium-137 in blood (pc./kg)}}$$

was found to average 5.99, with a range from 5.59 to 6.53. The variation in the value of  $f$  among individuals was less than either that of the body burden or the blood concentration, indicating a rather consistent value of the factor.

Day to day fluctuation of dietary intake of caesium-137 is very likely to occur and this can cause day to day fluctuation of blood concentrations because of a rapid transition of ingested caesium. An *in vivo* experiment on the metabolism of caesium in human blood was conducted in order to estimate the degree of fluctuation mentioned here<sup>6</sup>. The result suggested that possible errors would amount to up to 30 per cent in an estimate based on individual determination, but the use of a pooled blood sample representing a number of individual or an average for a number of individual determinations could afford a means of assessing the concentration in the population with satisfactory accuracy.

The validity of assessing the population concentrations of caesium-137 has become possible on the basis of blood analysis, and so a research project was initiated in November 1965 and a first series of collections of blood from the Far East and the Pacific region was made. It should be noted that the relation factor mentioned here is only valid for male, so that blood samples were collected from males only. Red Cross societies in these regions were requested to participate in the project and ten samples each were air-mailed to this Institute. The results of analyses are summarized in Table 1.

To estimate the body concentrations of caesium-137, the relation factor of 6 was multiplied by the blood concentration to get the body burden/unit body weight (pc/kg), which was then divided by an assumed concentration of potassium/unit body weight (2 g/kg) to obtain the concentration of caesium-137/g of potassium in the body (pc/gK). The total body burden is expressed in this way because most data are available in these units and for convenience in comparison.

In Table 2 are shown the estimates thus obtained for people in the Far East and the Pacific region. The values are comparable in magnitude with those obtained by whole body counting for other parts of the world except Norway (Table 3). Naturally, our knowledge of the latitudinal distribution of radioactive fall-out can never explain the variable concentrations found in different parts of the world even if local climatological circumstances such as rainfall are taken into consideration. One of the indications of such discrepancy can be found between the body concentrations in Japan and the Philippines or Thailand and Burma. Food habits are believed to be a cause of

such discrepancies and high consumption of sea food as a source of animal proteins has been considered to reduce the body concentrations of caesium-137, but further inquiry into the composition of the diets in respective countries is needed.

The method of blood analysis seems to be a useful means by which the worldwide information on the concentrations of caesium-137 in the general public can be obtained to determine the risks of radioactive materials discharged into the environment on a worldwide scale.

I thank the blood banks and blood transfusion services which took part in this project. This is part of a co-ordinated programme of research under a research agreement with the International Atomic Energy Agency.

## Host Specificity of *Sitona* Beetles

MEMBERS of the genus *Sitona* (Coleoptera: Curculionidae) are well known pests of leguminous plants. Their larvae are subterranean feeders and have been shown to feed on the root nodules, roots or both<sup>1-4</sup>. Observations I have made recently on *Sitona regensteinensis* Hbst. suggest that the feeding preference of its larva is not only restricted to the root nodule cells of the host plant (*Sarothamnus scoparius* L. Wimm), but to the cells containing bacteria.

Preliminary observations made by growing broom seedlings between glass plates and introducing larvae onto the soil surface showed that the larvae found their way down and fed only on root nodules. It was noticed that feeding was confined to the inner contents of the nodules and the outer regions were left as "coverings" or "skins". Examination of numerous root nodules from field samples showed that a larva pierces the nodule by eating its way through and feeds on the contents of the nodule after entering it. Once the contents of a nodule are fully consumed, the empty "skin" is abandoned and the larva shifts to a fresh nodule.

As the nature of the damage done by the larvae to the root nodules is not known, an investigation of this was made by taking sections of damaged and undamaged nodules and staining them. The nodules were doubly embedded in 'Celloidin' and paraffin; sections 10 $\mu$  thick were cut, and then stained with carbolthionin followed by orange G. This staining method was used by Stoughton<sup>5</sup> to demonstrate bacteria in plant tissue; the bacteria are stained deep blue, cellulose walls yellow or green and lignified tissue light blue. A normal undamaged nodule (Fig. 1) shows an epidermis, a narrow cortical region of parenchymatous cells, an endodermis, a pericycle and then a ring of vascular tissue; the region of the pith is occupied by cells filled with bacteria which are deeply stained. The bacteria-containing tissue which occupies the greater part of the nodule is clearly distinguishable in Fig. 1.

The examination of sections of the damaged (and abandoned) nodules (Fig. 2) revealed that the *Sitona* larvae have a specialized feeding habit in that they consume only the cells containing bacteria; the epidermis, cortex, endodermis and the vascular bundles are not eaten. Parts of a normal root do not seem to be included in the diet of a *S. regensteinensis* larva.

Fig. 2. Transverse section of damaged and abandoned root nodule of broom.

The preference of *Sitona* larvae for root nodules is not surprising from a nutritional point of view, because nodules contain bacteria and their function is nitrogen fixation. Nevertheless, it is interesting to note that nitrogen fixing nodules of leguminous plants contain a substance similar to haemoglobin and known as leghaemoglobin. The role and mode of this haemoglobin are unknown, but it is formed only in cells containing bacteria\*. In conclusion, these observations suggest an interesting relationship between the host plant and the pest, and the question arises as to whether the host specificity of *Sitona* beetles to legumes is associated with leghaemoglobin.

This work was carried out at Imperial College Field Station, Silwood Park, Ascot. I thank Professor O. W. Richards for providing facilities.

## Elimination of Foreign Particles by the Snail, *Helix aspersa*

Brown and Brown<sup>1</sup> have described techniques for investigating the elimination of foreign, non-metabolizable particles from the bodies of invertebrate animals and have applied these techniques to the sandy-beach snail, *Bullia*. In this prosobranch the particles are phagocytosed by macrophagic haemocytes which migrate to the exterior mainly through the wall of the heart into the pericardial cavity and then through the renopericardial canal into the kidney, leaving the body through the nephropore. Some migration also takes place through the mantle and into the kidney from the surrounding sinuses. Tripp<sup>2</sup>, using different techniques, found that in the fresh water pulmonate, *Australorbis*, laden amoebocytes migrate mainly through the mantle epithelia and adjacent surfaces. This work has now been extended to the terrestrial snail, *Helix aspersa*.

Large aestivating individuals of *Helix* were collected, caused to emerge by being placed over water in a cold-room, and fed on lettuce. The following day, 0.35 ml. of 'Thorotrast' (a colloidal suspension of thorium dioxide) was injected into the pedal sinus of each of twelve individuals, while a further three were subjected to injections of the same volume of gastropod Ringer and retained as controls. The animals were kept on damp lettuce throughout the experiment, at a temperature of 15° C ( $\pm 1.0$ ). A test animal was killed each day for 12 days and preserved in alcohol; radiographs of each animal were taken later by means of a Siemens diagnostic X-ray machine with an exposure of 2.0 sec at 60 kV and 16 m.amp; the shutter-to-film distance was 120 cm.

In radiographs of snails killed within 48 h of injection, no pattern of internal organs is visible and the entire body casts a single, diffuse shadow. By the third day, however, certain of the organs and tissues cast hard shadows, in contrast with the rest of the body, and these shadows reach maximum intensity by the fourth or fifth day. The shadows then fade and by the tenth day are barely distinguishable from the shadow cast by the body as a whole. Even after 12 days, however, the body of the snail is more opaque to X-rays than is a control animal killed at the same time, indicating that some thorium remains in the tissues after that period.

In test animals, the organs which cast the most intense shadows are the reproductive organs, particularly the penis and the lower part of the female duct, including the vagina, and the mantle. In some animals, part of the mid-gut can also be seen in the radiographs. Sections through various regions of the reproductive organs, viewed by the method of Baxter<sup>3</sup>, reveal thorium-laden amoebocytes in the walls of these organs throughout their length, but particularly in the female side of the common duct. The intense shadows cast by the vagina and penis are seen to be caused not so much by laden haemocytes migrating through the walls of these structures as by an accumulation of them in the lumina of the ducts. Sections also reveal thorium-laden cells in the mantle epithelia and in the wall of the mid-gut, though they are relatively rare in the lumen of the alimentary canal. The heart does not appear to be involved at all as a migratory pathway and the involvement of the kidney is either very slight or lacking altogether.

In all three species of gastropod examined the mantle epithelia are involved in the elimination of foreign particles, but here the similarity ends. The chief route taken by migrating amoebocytes in *Bullia*, starting through the wall of the heart, is not evident in either *Australorbis* or *Helix*; in the former snail the mantle epithelium is of great importance as a migration route, but in *Helix* other pathways are exploited and the burden on the mantle epithelium appears to be no greater than in *Bullia*. It may be argued from this evidence that the importance of the mantle epithelium as a migratory pathway is related

to the closeness of the snail's association with water; however, work in progress on a variety of intertidal prosobranchs indicates that the relationship is by no means as simple as such a statement may suggest. Nevertheless, the chief migratory pathways in a terrestrial snail like *Helix* could be expected to differ from those found in aquatic snails, an expectation which is fully supported by the foregoing evidence.

Of particular interest is the use of the reproductive organs as a migratory route in *Helix*. Not only are these organs not involved in either *Bullia* or *Australorbis*, but their use for the elimination of foreign particles appears to be unknown also among the lamellibranchs<sup>1</sup>. The accumulation of laden haemocytes in the lower regions of the reproductive organs is clearly temporary, for the shadows cast by the penis and vagina have both disappeared by the tenth or eleventh day after injection. The fact that there was no accumulation of haemocytes in the gut may be accounted for by the conditions in which the experiment was conducted, the animals being allowed to eat as much as they wished after a period of aestivation; presumably the rapid translocation of food through the gut carried away haemocytes which had migrated through its walls.

I thank Professor P. E. S. Palmer and the staff of the Department of Radiology at Groote Schuur Hospital for their help.

### Insect Population Control by the Use of Sex Pheromones to inhibit Orientation between the Sexes

SEVERAL people have speculated on the thesis that if a sufficiently high concentration of an insect sex pheromone could be maintained in the atmosphere, the sexes could not find each other for mating purposes<sup>1-3</sup> (for a review, see Jacobson<sup>4</sup>). Their conclusion was that this could lead to control or possibly eradication of the species. In the only large scale experiment to test this principle, gyplure, an analogue of the gypsy moth sex pheromone, was distributed over an island infested with gypsy moths<sup>5</sup>. Mating of males with females was not prevented; the failure of this experiment was attributed to the presence of a "masking" substance in the synthetic pheromone<sup>6</sup>. We have for the first time obtained experimental confirmation that pre-mating communication between the sexes can be disrupted by permeating the atmosphere with an insect pheromone. This general phenomenon was demonstrated using *Trichoplusia ni* (Hübner), the cabbage looper, as the test organism.

The experiment was carried out in a 27 m<sup>2</sup> plot which was cross-hatched with 100 stakes set at 3 m intervals. Each stake was about 1 m above the ground. A stainless steel ringed planchet, 25 mm in diameter, was attached to the top of each stake. A cylindrical trap, 11 cm in diameter and 64 cm long, of a design suggested by Howland (personal communication) was placed at an elevation of 1 m in the centre of the plot. The trap was divided into three compartments of equal length. The centre compartment, separated from the end compartments by a copper screen, contained ten virgin *T. ni* females. The open end compartments were lined with a sticky material. The experiment was carried out during a period of six nights. At the start of the experiment 20 µl., about 17 mg, of synthetic *T. ni* pheromone<sup>7</sup> was added to each of the 100 planchets. Each planchet was covered with wire gauze to prevent stimulated males from falling into the phero-

none. At the start of the fourth night, an additional 10 µl. of pheromone was added to each planchet. An identical plot 600 m away with a female baited trap, but without synthetic pheromone, was used as a check on male *T. ni* activity. The locations of the pheromone-treated and the check plots were randomized every other night. The female traps in the check plots caught a total of 102 *T. ni* males whereas the female traps in the pheromone-treated plots caught no *T. ni* males.

The absence of *T. ni* males in the female traps in the treated plots is interpreted as indicating that the synthetic pheromone concentration in the air was sufficiently high to prevent *T. ni* males from orienting to the additional increment of pheromone released by the living females. The females probably were prepared for mating and released pheromone during the time interval between 10 p.m. and 5 a.m.<sup>8</sup>. The temperature range during that time for the experiment was 21° C to 9° C. At these temperatures the pheromone release rate ranges from 110–40 µg h<sup>-1</sup>/planchet with the lowest release rate for one night being 57–40 µg h<sup>-1</sup>/planchet (unpublished work of Gaston, Shorey and Saario). Experiments are in progress to establish the minimum pheromone concentration required to prevent male orientation to females.

The successful disruption of male orientation to females may be caused by sensory and (or) central nervous system adaptation to the pheromone. In addition, the relatively large concentration of pheromone near the individual planchets could have caused the males to orient there rather than to the females.

The result of this experiment indicates that economic control of an insect over large areas may be possible by behavioural control using sex pheromones. Large scale release of sex pheromones presents numerous potential problems: (a) cost of pheromone; (b) cost of distribution; (c) how to keep a sufficiently large concentration of pheromone in a large area, and (d) mammalian hazards. Since a large part of the cost of the behavioural control method may be in the distribution system, the pheromones of two or more different insect species can be distributed as economically as one.

We wish to express our appreciation to the U.S. National Institutes of Health for supporting this work through a grant.

### New Phenolic Plant Growth-regulating Compounds

It has been reported that 2,6-dichlorophenol and the corresponding dibromo- and diiodo- compounds show appreciable activity in promoting cell elongation when examined in the pea segment and pea curvature tests, and that they induce severe epinastic responses when applied through the soil to tomato plants<sup>1</sup>. Further work has now revealed other 2,6-substituted phenols which are active in these tests. Thus, in the pea tests, 2-chloro-, 2-bromo- and 2-iodo-6-nitrophenols possess activities approaching that of 2,4-dichlorophenoxyacetic acid (2,4-D); the corresponding 6-cyanophenols are also active (Table 1). 2-

Methyl-6-nitrophenol is inactive in the pea tests over the concentration range investigated, but replacing the methyl by trifluoromethyl, a strongly electron-attracting group, confers appreciable activity (Table 1). 2,6-Dinitrophenol is very phytotoxic and was reported inactive in our earlier tests<sup>1</sup>. At very small concentrations, however, it does show activity in the two pea tests, although it is completely inactive in the wheat cylinder test. (For details of all bioassay methods used see Fawcett *et al.*<sup>2</sup>.)

From all our results, for a phenol to show appreciable growth-regulating activity in the pea tests, both positions in the ring *ortho* to the hydroxyl group must be occupied by electron-attracting groups, although it would appear that certain steric requirements must also be fulfilled, because when one or both of the *ortho* substituents in the ring is fluorine the compound is inactive (Table 1). While in some cases a *meta* position in addition to the two *ortho* positions may be substituted by halogen or nitro without complete loss of activity, results already reported and all those of our more recent work indicate that the *para* position must not be substituted for the compound to be active.

As already reported<sup>1</sup>, 2,6-dichloro-, dibromo- and diiodo-phenols, in addition to exhibiting activity in the pea and tomato tests, show slight activity in the wheat cylinder test. When one of the halogens is replaced by —NO<sub>2</sub> or —CN, however, the compounds are appreciably active in the pea tests, but are completely inactive in the wheat test. Epinastic responses are observed with the above-mentioned nitro compounds when applied in 1 per cent solution in lanolin to the stem of tomato plants and also when applied in aqueous solution to the soil. With the corresponding cyano compounds the epinastic responses in tomato plants are transitory and disappear within 48 h. Furthermore, no effects are observed when these cyano compounds are applied as aqueous solutions of their sodium salts to the soil of potted tomato plants at the rate of 2.5 mg/pot (6 in. diameter). Such observations indicate that the molecules are rendered inactive both in tomato plants and in the soil.

Metabolism experiments with 2-bromo-6-nitro- and 2,6-diiodo-phenols in wheat coleoptile and pea stem tissue have indicated that in the former tissue, hydroxylation of the *para* position occurs. Thus, for example, we have shown by chromatographic techniques that 2-bromo-6-nitrophenol is rapidly converted in wheat coleoptile tissue to 2-bromo-6-nitro-1,4-hydroquinone. This compound has been synthesized and as expected,

having a *para* position substituted, it has no growth-regulating activity. 2,6-Diiodophenol is similarly converted in this tissue to 2,6-diiodo-1,4-hydroquinone which again is completely inactive. We have found that such inactivation does not occur readily in pea tissue, thus accounting, at least in part, for the activity of these phenols in the pea tests.

## SOIL SCIENCE

### Diffusion of Potassium from Mica-like Clay Minerals

DIFFUSION coefficients for the release of potassium from phlogophite and biotite in the range 1 to 50 × 10<sup>-10</sup> cm<sup>2</sup>/sec have been reported by Rausell-Colom, Sweatman, Wells and Norrish<sup>1</sup>. Similar measurements have not yet been obtained for muscovite or its counterpart in soils, the fine grained materials generally referred to as illite.

We have conducted a number of experiments on the rate of release of potassium from the fraction of Fithian illite (*API* 35) less than 2 micron, and an illite from Tumut, New South Wales, supplied by Dr. K. Norrish. The potassium contents of these micas are respectively 4.7 and 7.4 per cent.

Samples (0.75 g) were shaken in 200 ml. of 0.3 and 0.03 normal sodium chloride solution at 20°, 40° and 60° C. To keep the potassium concentration in the external solution to a minimum, 180 ml. of sodium chloride was replenished daily, and the solution was analysed for potassium using an 'SP 900' flame photometer. In Fig. 1, the amount of potassium released per day from the Fithian illite to the solution is given in relation to time; the potassium released at 20° C in 0.3 normal sodium chloride falls to about 5 µequiv./g/day within 4–6 days to give a solution concentration of approximately 2 × 10<sup>-5</sup> molar. Similar curves were obtained for the Tumut illite, but because the mean

Results in the pea segment test are expressed as the percentage of the final length of the control segments.

Results in the pea curvature test are assessed on an arbitrary scale of 0 (inactive) to 6 (highly active). T signifies that toxic effects were observed. Figures significantly different from the control are indicated thus:

\* At 5 per cent level.

† At 1 per cent level.

‡ At 0.1 per cent level.

Fig. 1. Rate of potassium release from Fithian illite. ---, 0.3 normal sodium chloride; —◇—, 0.03 normal sodium chloride; —△—, 20° C; —◇—, 40° C; —○—, 60° C.

particle size was larger than the Fithian illite the actual amount of potassium released to the solution was correspondingly less.

Most measurements were carried out at the pH of the sodium chloride solution (pH 5.7). No observable changes in the rate of potassium release occurred in the pH range 4-8.

The experimental observations indicated that release of potassium was controlled by diffusion; thus to calculate diffusion coefficients, a model was adopted based on radial diffusion in a cylinder in which the concentration of potassium on the cylindrical surface is constant, and initially the concentration of potassium throughout the cylinder is uniform. It is assumed that the diffusion of potassium through the upper and lower faces of the cylinder (corresponding to external cleavage faces) is negligible. Following Crank<sup>3</sup>, if  $a$  is the radius of the cylinder,  $M_t$  is the quantity of diffusing substance which has left the cylinder in time  $t$  and  $M_\infty$  is the corresponding quantity after infinite time, then,

$$\frac{M_t}{M_\infty} = \frac{4}{\pi^{\frac{1}{2}}} \left( \frac{Dt}{a^2} \right)^{\frac{1}{2}} - \frac{Dt}{a^2} - \frac{1}{3\pi^{\frac{1}{2}}} \left( \frac{Dt}{a^2} \right)^{\frac{3}{2}} \dots \quad (1)$$

For the relatively short times in our experiments the third and subsequent terms may be ignored, and therefore

$$\frac{M_t}{M_\infty} = \frac{4}{\pi^{\frac{1}{2}}} \left( \frac{Dt}{a^2} \right)^{\frac{1}{2}} - \frac{Dt}{a^2}$$

or

$$\frac{1}{t} \left( \frac{M_t}{M_\infty} \right) = \frac{4}{\pi^{\frac{1}{2}}} \left( \frac{D}{a^2} \right)^{\frac{1}{2}} \frac{1}{t^{\frac{1}{2}}} - \frac{D}{a^2} \quad (2)$$

and thus a plot of

$$\left( \frac{M_t}{M_\infty} \right) / t \text{ versus } \frac{1}{t^{\frac{1}{2}}}$$

should give a straight line with a slope

$$\frac{4}{\pi^{\frac{1}{2}}} \left( \frac{D}{a^2} \right)^{\frac{1}{2}} \text{ and intercept } -\frac{D}{a^2}.$$

Consequently if  $a$  is known  $D$  may be calculated from both the slope and intercept (Fig. 2).

In practice the values obtained from the intercept may vary considerably for two reasons: the actual magnitude of the intercept is very small, and this gives rise to uncertainty from scale errors and because the diffusion equation is not strictly obeyed during the initial period of potassium release (up to an hour). The diffusion equation

is not strictly obeyed because of mass action exchange between sodium and potassium at sites on the external surface of the illite particles. The magnitude of this effect

may be estimated from the straight line plots of  $\frac{M_t}{M_\infty}$  versus  $t^{\frac{1}{2}}$ ; if the diffusion equation is obeyed from time zero, the line should pass through the origin. The actual intercept on the ordinate is a measure of the amount of potassium initially released from surface sites on the external surface of the crystal or frayed crystal edges. The final values for the diffusion coefficients have therefore been calculated from the slopes (Fig. 2) after allowance for this effect.

The values for mean particle radius ( $a$ ) were calculated from nitrogen surface area measurements on the assumption that there was a 10:1 ratio between particle diameter and thickness<sup>2</sup>. This assumption was confirmed by observation of shadowed particles in the electron microscope. For the < 2 $\mu$  fraction of Fithian and Tumut illite the mean particle radii were 500 and 1,800 Å respectively.

Fig. 2 shows the potassium release data in Fig. 1 plotted according to equation (2). Each curve results from a single experiment.

The mean diffusion coefficients at 60° C calculated from a number of experiments are  $7.7 \pm 2.8 \times 10^{-20}$  and  $1.1 \pm 0.5 \times 10^{-20}$  cm<sup>2</sup>/sec for 0.3 and 0.03 normal sodium chloride respectively. (Errors quoted are at the 95 per cent confidence level.)

Under similar conditions the diffusion coefficients for the Tumut illite were the same within experimental error for the 0.3 normal solution and were a factor of two higher for the 0.03 normal solution.

These values of the diffusion coefficients for potassium release from illites are therefore comparable with those for the diffusion of hydrogen in nickel and iron hydroxides<sup>4</sup> and are about ten orders of magnitude lower than for potassium release from biotite.

This difference may be explained from the observation of Bassett<sup>5</sup> that the dipole moments of the hydroxyl ions in trioctahedral micas are perpendicular to the cleavage, whereas those in muscovite, a dioctahedral mica, are obliquely oriented, and as a result the proton is further from the ion and places the negative or oxygen end of the dipole closer to the potassium with a resulting increase in binding energy.

## Effects of Pulverized Fuel Ash on the Moisture Characteristics of Soils

THE available water capacity (AWC) of a soil has been shown to be positively correlated with the percentage of fine sand (0.2-0.02 mm) and organic carbon present, and negatively correlated with the percentage of coarse sand (2.0-0.2 mm)<sup>1</sup>. Pulverized fuel ash, produced from the combustion of finely ground coal, is a dust containing between 50 and 70 per cent of "fine sand" size particles<sup>2</sup>. It occurred to us that pulverized fuel ash could be applied to increase the AWC of coarse textured soils. To test this hypothesis a field experiment was carried out on a coarse sandy loam of the Newport Series. Rates of ash, equiva-

lent to 0, 50, 100 and 200 tons/acre, and containing 65 per cent of particles of size 0.2–0.02 mm, were incorporated into the top 12 in. of soil in small plots by putting soil and ash through a concrete mixer. There were five replications of each treatment. A satisfactory crop of red beet was grown on all plots, but there was a reduction of 9 per cent in the yield of roots with the highest rate of ash applied, which was probably caused by the presence of toxic quantities of boron. After harvest the various moisture characteristics of the soil were determined<sup>3</sup>: the upper limit of available water by the gravimetric method on samples taken 48 h after rewetting and the lower limit by the 15 atm. percentage method.

The largest addition of ash significantly increased the AWC and there were small but non-significant increases with the lower rates of application (Table 1). This effect resulted from the progressive increase in the moisture retained at the upper limit of available water with increasing quantities of ash; there was little effect on the 15 atm. percentage.

To assess the effect of ash on other soils as quickly and simply as possible, experiments were carried out in the laboratory. First, to determine whether an effect comparable with that obtained in the field could be obtained under laboratory conditions, a quantity of the soil from the site of the field experiment was air-dried. Ash was mixed with the soil at rates equivalent to 0, 50, 100, 150, 200 and 300 tons/acre in the top 12 in. of soil. After thorough wetting, triplicate samples of each mixture were subjected to a suction of 0.05 atm. to determine the upper limit of available water<sup>3</sup>; the bulk density was obtained from the same samples and the 15 atm. percentage determined from a further three samples.

The suction of 0.05 atm. gave lower values for the upper limit of available water than the gravimetric method under the conditions of this experiment and for this reason the measured AWC of the untreated soil under field conditions was 1.29 in. (Table 1) but only 1.11 in. in the laboratory study (Table 2). Differences of a similar order of magnitude were obtained with comparable ash treatments. Nevertheless, the percentage increase in AWC resulting from the addition of ash in the laboratory was greater than those obtained in the field and possibly resulted from the better mixing of ash and soil that could be achieved in the laboratory. Despite differences in magnitude, the results from the two types of experiment were similar and therefore the effect of ash on four other coarse textured soils was assessed using the same laboratory techniques; the results are given in Table 2.

Without exception the AWC of all soils increased progressively with increasing quantities of ash, the relationship between AWC and the rate of ash applied being

Table 1. EFFECT OF PULVERIZED FUEL ASH ON THE MOISTURE CHARACTERISTICS OF THE TOP 12 IN. OF A COARSE SANDY LOAM

Standard error of differences between treatments within a soil = ±0.122 (20 d.f.)

approximately linear for three soils and possibly curvilinear for two soils. The largest increase in AWC occurred when ash was added to the coarsest textured soils (those having only small percentages of fine sand present in their natural state) and smaller, though still significant, increases occurred on the slightly heavier soils.

Further work is proceeding on other soils under field conditions to study the relationships between rate of ash application, increase in AWC and the particle-size composition of different soils and to determine whether better growth of crops and higher yields are obtained from soils with AWCs increased in this way.

Although much work has been carried out on the phytotoxicity associated with the high boron contents of some ashes and on the nutrient status of pulverized fuel ash in relation to crop growth, particularly where ash has been used as a filling material in land reclamation<sup>2</sup>, its use in comparatively small quantities to alter the moisture retaining properties of soil does not appear to have been considered. Provided any problem of phytotoxicity, particularly from excess boron, can be overcome and if the beneficial effects of pulverized fuel ash on AWC are confirmed and result in increased crop yields, then pulverized fuel ash could have an important use as a soil improver. For example, its application on the cultivated sand lands in areas of low rainfall in Britain<sup>5</sup> may reduce the need to irrigate crop plants. Further, with the aforementioned proviso, it may possibly be used to improve the productivity of the marginal sand lands, that is, soils characterized by poor water retention and high acidity which make up more than 800,000 acres of England and Wales<sup>6</sup>; the addition of highly alkaline pulverized fuel ash<sup>2</sup> may simultaneously increase the water retention of these soils and reduce the high acidity.

We thank Dr. E. W. F. Gillham of the Central Electricity Generating Board for kindly providing the pulverized fuel ash and for the data on the particle-size composition of the ash.

## APPLIED SCIENCE

### Tensile Strength of Granular Materials

Smalley and Smalley<sup>1</sup> have commented on a theoretical expression for the tensile strength of an ideal granular material (in the pendular stage of moisture distribution), due to Rumpf<sup>2</sup>, and have proposed an alternative approach. Their final equation 10a, namely,

$$\sigma \approx 4.6 \frac{Bt}{D^3}$$

(where  $B$  is the interparticle force per contact,  $D$  is the diameter of the particles, and  $t$  is the thickness of the fracture zone) includes in the constant term the value of the co-ordination number,  $k$ . The authors quote a value  $k = 8.5$ , taken from data published by Bernal and Mason<sup>3</sup>; my re-examination of these data (given in Table 1, ref. 3) indicates that the value should be  $k = 8.0$ , which makes a proportionate change in the constant of equation 10a. While equation 10a is dimensionally consistent, the authors' intuitive reasoning in their final paragraph<sup>1</sup> would seem to require that  $\sigma$  be inversely proportional to  $D^2$  and not  $D^3$ , as the number of bonds in a section of constant size is inversely proportional to particle cross-section, and not volume; in this respect, Rumpf's

equation  $\sigma \approx 2B/D^2$  is more plausible, though of rather academic interest. Rumpf<sup>2</sup> measured the tensile strengths of limestone pellets, and found that as moisture content decreased, so also did the strength, contrary to his theoretical expectations for the pendular state. I have determined the tensile strengths of various size fractions of a fine coal, using a split cylinder method. Fig. 1 illustrates some typical results, which show a trend similar to that found by Rumpf for limestone.

Quite recently, Tanaka *et al.*<sup>4</sup> have published a theory, together with some results of measurements made on a fly ash; the measured strengths tend to zero as moisture contents become very small and the authors remark that this is consistent with the theory they propound. I submit that the qualitative agreement cited by these authors is fortuitous, because their theory is crucially dependent on the fallacious premise that at low water contents capillary pressure can be ignored when calculating the cohesive force between two spheres having a lens of water at their point of contact. Fisher<sup>5</sup> was the first to deduce theoretically that both the tension in the air-water interface and the pressure deficiency must be considered, and that as the water lens diminishes the cohesive force between two spheres increases to the limiting value  $B = \pi DT$  ( $T$  = surface tension), just before dryness (when molecular dimensions are reached and elementary theory becomes inapplicable). Cross and Picknett<sup>6</sup> have convincingly confirmed this experimentally. Despite the seeming contradiction, it can be concluded that the tensile strength characteristics reported here, and in refs. 2 and 4, are typical of real granular materials.

Consider first a pendular distribution of moisture achieved by removing liquid from a rigid assembly of particles, initially in the saturated condition. It is to be expected that once the pendular stage is reached, decreasing the moisture content results in the gaps between neighbours not quite in contact progressively (according to their size) ceasing to be bridged by liquid; while the strengths of the remaining bridges presumably approach the theoretical maximum value ( $\pi DT$  for spheres), the number of "dry joints" increases and could result in a net

decrease in the tensile strength of the assembly. If the spatial distribution of near neighbours is known<sup>7</sup>, then the "strength versus liquid content" characteristic for the case of spherical particles should be amenable to computation.

It seems necessary, however, to differentiate between the foregoing "static" method of forming the moist agglomerate, and the more usual "dynamic" processes, in which granules and moisture are mixed together and then consolidated (as in the tests yielding the data given in Fig. 1). Consider now the hypothetical case of such a consolidation process resulting in an assembly of particles identical with that obtained for the static method: then at identical moisture contents in the pendular state, the occurrence of "dry joints" is more likely in the "dynamic" than in the "static" process, because particles, or rather the liquid films surrounding them, must now make direct contact before a liquid bridge can be established. The formation of a bridge decreases the film thicknesses on the two particles, and to some extent reduces the number of subsequent bridges formed. Thus the dynamic assembly should have lower tensile strength than the static assembly, and this should decrease as moisture content diminishes. If the particles are not perfectly wetted, even direct contact is not a guarantee of bridge formation, and when bridges do form liquid may be completely withdrawn from other sites on the surfaces of the particles, so that subsequent encounters during the compaction process are even less likely to result in bridges.

The final number of bridges, in a given cross-section, for the dynamic case of perfectly wetted spheres may be soluble using an incremental mathematical technique and given the end point spatial distribution and the amount of liquid present; for imperfectly wetted spheres some assumptions would have to be made concerning the liquid distribution at the start of compaction. It is unlikely that the case of imperfectly wetted, irregularly shaped particles could be better than very approximately treated.

I thank Dr. Cutress for helpful comments.

## GENERAL

### Normal or Log-normal: Appropriate Distributions

I WISH to point out that for the statistical analysis of certain types of data the assumption that the data are drawn from a normal population is usually wrong, and that the alternative assumption of a log-normal distribution is better. This alternative is widely used by statisticians, economists and physicists, but for some reason is often ignored by scientists of some other disciplines.

The normal distribution is unlikely to hold for the class of data in which the possible range of values is closed at the lower end, for example by zero or the concentration required to maintain life, but is effectively open at the higher end, and the empirical mean lies near the lower limit. One expects in such cases an asymmetric distribution with a "tail" of high values. Concentrations of many materials in body fluids are in this class. Particular examples are glutamate-oxaloacetate transaminase<sup>1</sup> and

free fatty acids<sup>2</sup> in rat plasma, and dieldrin in human blood and fat<sup>3</sup>. The normal distribution is plainly not applicable. Not only is the observed distribution asymmetric, but in two cases<sup>1,2</sup> the standard deviations are such that in large samples more than 10 per cent of the values would be expected to be negative, which is, of course, impossible.

These examples have been tested for log-normality. For two<sup>1,2</sup> the log-normal distribution holds. For the third<sup>3</sup> it is much better, but some tailing remains. Several other less conclusive cases have come to my attention (for example, isopropoxyphenol equivalents in human urine<sup>4</sup>), and in none is the log-normal distribution worse than the normal.

I suggest that when an *a priori* decision about distribution has to be made the log-normal distribution should always be preferred to the normal distribution for data of this general type. (The choice is trivial when the standard deviation is less than 15 per cent of the mean value, because the results of tests are very nearly the same.)

For calculations the logarithms of the data are treated in exactly the same way as the original data when a normal distribution is assumed. The mean obtained, the antilog (mean log), is the geometric mean. Standard deviations may either be expressed as ranges, for example, geometric mean = 2, standard deviation range = 1-4; or all the results may be given in logarithms, in this example: mean log ( $\pm S.D.$ ) =  $0.30 \pm 0.30$ . A *t*-test gives the significance of the difference between logarithms, and thus the significance of the ratio of the values corresponding to the logarithms.

It should be emphasized that for data the range of which is open at one end it is better when in doubt to use logarithms; but when the range is closely restricted at both ends, as, for example, in the case of percentages, the normal distribution is likely to be better, and any other distribution including the log-normal should only be used when there is statistically significant evidence from the data in its favour.

## Random Generation of Optimal Codes

THE problem dealt with in this communication is that of generating an optimal code for the transmission of a long sequence of binary digits over a noisy channel. The channel is supposed to produce errors at random,  $p$  ( $< \frac{1}{2}$ ) being the probability that a particular digit is wrong, and  $q$  ( $= 1 - p$ ) being the probability that it is right. The capacity of such a channel is

$$(p \log p + q \log q) - \left(\frac{1}{2} \log \frac{1}{2} + \frac{1}{2} \log \frac{1}{2}\right) = 1 - X \text{ bits per digit,}$$

where  $X = -(p \log p + q \log q)$  lies between 0 and 1, and all logarithms are referred to the base 2. Consequently, if it is desired to transmit  $B$  bits of information reliably, a total of  $N$  digits must be sent, where  $N > B/(1 - X)$ . One way of doing this is to begin by sending  $B$  message digits, and to follow them with  $C$  checking digits, where  $C = N(X + \delta)$  and  $\delta$  is a positive finite number. Then  $B/N = 1 - C/N = 1 - X - \delta < 1 - X$  as required. The checking digits are made to depend on the message digits so as to enable the recipient, in spite of the transmission errors, to reconstruct the complete set of  $N$  digits with virtual certainty. The question is: can this be done with a number of checking digits which is

close to the theoretical minimum? In other words, is it possible to specify an actual coding procedure such that when  $N$  is sufficiently large  $\delta$  can be made arbitrarily small? It is possible, and I now describe such a procedure.

Set  $C$  equal to  $N(X + \delta)$ , and proceed to treat  $\delta$  as a small positive quantity. Now set up a matrix  $M$  with  $B$  rows, corresponding to the  $B$  message digits, and  $C$  columns, corresponding to the  $C$  checking digits. Each element of the matrix is assigned the value 0 or 1 according to the toss of a coin, so that each row may be read as a random binary number in the range 0 to  $2^C - 1$ . The sender uses the matrix  $M$  for assigning values to the  $C$  checking digits. If  $d_b$  is the  $b$ th message digit, then the  $c$ th checking digit is assigned the value 0 if  $\sum_b d_b M_{bc}$  is even and the value 1 if it is odd. The complete sequence of  $N$  digits is then transmitted.

When the message arrives the recipient tests the  $C$  checking digits against the others to see if they satisfy the appropriate parity relations. If the message is long (as we are assuming), about half these relations will be violated. A possible interpretation of the observed disparities is that all the errors of transmission have occurred in the checking digits; but this interpretation is highly implausible, because the total number of errors in the message will almost always be close to  $pN$ , which is substantially less than  $\frac{1}{2}C$ , by virtue of the fact that when  $p < \frac{1}{2}$ ,  $p < -\frac{1}{2}(p \log p + q \log q)$ . The recipient's best policy is to search among the  $N$  digits for a set of about  $pN$ , such that if they were all wrong, and the others all right, the resulting disparities would be precisely those observed. The search will not, however, be worth undertaking at all unless the recipient can be assured that if he finds an interpretation of the observed disparities which implicates about  $pN$  digits, this interpretation is indeed correct. Such an assurance emerges from the following argument.

Suppose that the recipient's search has been rewarded by the discovery of a certain set of digits, numbering about  $pN$ , such that if these digits, and no others, were altered, the disparities would all disappear. The prior probability of these particular digits being wrong, and all the others right, is  $p^{pN}q^{qN}$ . The prior probability of the sequence having been corrupted in any other manner is therefore  $1 - p^{pN}q^{qN}$ . But because  $M$  is a random matrix the probability of any other corruption resulting in the observed disparities is  $2^{-C}$ . Hence the odds on the recipient's provisional interpretation being right are

$$p^{pN}q^{qN} : 2^{-C} (1 - p^{pN}q^{qN}),$$

which for large  $N$  becomes  $2^C p^{pN}q^{qN} : 1$ . But by construction

$$C = N(\delta + X) = N(\delta - p \log p - q \log q).$$

Therefore as  $N$  tends to infinity the odds in favour of the provisional interpretation, namely,  $2^{N\delta} : 1$ , become infinite. Hence there is no need for the recipient to continue the search.

It is always possible, of course, that the number of erroneous digits in the sequence is substantially greater than  $pN$ , or that there are two or more alternative interpretations of an observed set of disparities, both interpretations implicating about  $pN$  digits. These possibilities, however, become more and more improbable as  $N$  increases, so that the random matrix code here described is indeed optimal in the strict sense. As an engineering proposition it suffers from the grave disadvantage that the recipient is given no guidance as to how to conduct his search for the offending digits; but with sufficient patience he could in principle locate them by the exhaustive enumeration of all possible sets containing about  $pN$  members.

## FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

## Monday, March 20

INSTITUTE OF ELECTRICAL ENGINEERS (joint meeting with the Royal Society and the I.E.R.E. Computer Group, at Savoy Place, London, W.C.2), at 2.30 p.m.—Colloquium on "Automated Cartography: Scientific Needs and Engineering Possibilities".

INSTITUTE OF ACTUARIES (in Staple Inn Hall, High Holborn, London, W.C.1), at 5 p.m.—Prof. P. G. Moore: "Operational Research in Business".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5 p.m.—Dr. P. S. Hewlett: "Synergism and Potentiation in Insecticides".

BRITISH SOCIETY FOR THE HISTORY OF SCIENCE (in the Council Room of the Science Museum, Exhibition Road, London, S.W.7), at 5.30 p.m.—Dr. Sydney Smith: "Charles Darwin's 'Species' Work 1837-1842".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"Rendez-vous du Diable" (colour film).

PLASTICS INSTITUTE, LONDON SECTION REINFORCED PLASTICS SUB-GROUP (at the Eccleston Hotel, London, S.W.1), at 7.30 p.m.—Mr. F. Bennett: "Monomer Approach to Flame Retardancy".

## Monday, March 20—Tuesday, March 21

GRIMSBY COLLEGE OF TECHNOLOGY (at Nuns Corner, Grimsby)—Symposium on "Modern Developments in Food Preservation".

## Monday, March 20—Wednesday, March 22

BIOCHEMICAL SOCIETY (at Trinity College, Dublin)—469th Meeting. Included in the programme will be an Ordinary Meeting and a Discussion Meeting on "Metabolic Role of Vitamin A".

## Tuesday, March 21

UNIVERSITY OF SURREY (at the University of Surrey Annexe, 14-16 Falcon Road, Battersea, London, S.W.11), at 5.30 p.m.—Prof. E. Gutmann (Czechoslovak Academy of Science): "Problems of the Specificity of the Neuromuscular System".

INSTITUTE OF ELECTRICAL ENGINEERS (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion Meeting on "Rapid Fault Diagnosis of the Future", opened by Commander L. E. Land, R.N., and Mr. A. J. Cope.

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (joint meeting with the HEAVY ORGANIC CHEMICALS GROUP, at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Dr. M. M. Baizer (U.S.A.): "Electrolytic Reductive Coupling of Acrylonitrile".

SOCIETY FOR ANALYTICAL CHEMISTRY, SPECIAL TECHNIQUES GROUP (in the Lecture Theatre "C", Chemistry Department, Imperial College of Science and Technology, London, S.W.7), at 7 p.m.—Dr. G. Nickless: "Principles and Practices of Mössbauer Spectroscopy"; Dr. T. C. Gibb: "Mössbauer Spectra of Elements other than Iron and Tin".

## Tuesday, March 21—Thursday, March 23

ROYAL INSTITUTION OF NAVAL ARCHITECTS (in the Weir Hall, 10 Upper Belgrave Street, London, S.W.1)—Spring Meeting.

## Wednesday, March 22

CHEMICAL SOCIETY (at the University of Keele, Keele, Staffordshire), at 10.30 a.m.—Symposium on "Heterocyclic Chemistry".

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5 p.m.—Dr. I. J. Good: "A Bayesian Significance Test for Multinomial Distributions".

INSTITUTE OF ELECTRICAL ENGINEERS (at Savoy Place, London, W.C.2), at 6.30 p.m.—Dr. R. Spence and Mr. P. J. Baxandall: "The Theory of Oscillators".

INSTITUTE OF ELECTRICAL ENGINEERS (at Savoy Place, London, W.C.2), at 5.30 p.m.—Prof. A. M. Angelini: "The Development of Electricity Supply in Italy".

UNIVERSITY OF LONDON (at the Institute for Child Health, Gullford Street, London, W.C.1), at 5.30 p.m.—Mr. R. G. Burwell: "The Scientific Basis of Bone Homotransplantation".

INSTITUTE OF ELECTRONIC AND RADIO ENGINEERS, ELECTRO-Acoustics GROUP (at 8-9 Bedford Square, London, W.C.1), at 6 p.m.—Mr. K. O. Bäder: "Dynamic Properties of Audio Frequency Compressors".

INSTITUTE OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (joint meeting with the GRADUATE AND STUDENT SECTIONS OF THE INSTITUTIONS OF CIVIL AND OF MECHANICAL ENGINEERS, at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 6.15 p.m.—Mr. Ove Arup, C.B.E.: "Design".

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP—FOOD ENGINEERING PANEL (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Annual General Meeting and Chairman's Address.

## APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

BIOLOGIST, SCIENTIFIC OFFICER or SENIOR SCIENTIFIC OFFICER grade in the SYSTEMS SYNTHESIS SECTION of the DEPARTMENT of ECOLOGY, to work on theoretical aspects of plant and crop growth—The Secretary, Grassland Research Institute, Hurley, Maidenhead, Berkshire (March 24).

SENIOR LECTURER (preferably medically qualified and an interest in human physiology) in the DEPARTMENT of PHYSIOLOGY—The Secretary, The University, Aberdeen (March 25).

BIOCHEMIST (with at least D.Sc. or Ph.D. in biochemistry) at the National Nutrition Research Institute, South African Council for Scientific and Industrial Research, Pretoria, for duties which will involve studies of the biochemical and metabolic effects of various toxins (mainly mycotoxins) on the tissues of experimental animals and of man—The South African Science Office, Chichester House, 278 High Holborn, London, W.C.1 (March 28).

LECTURER (preferably with experience in X-ray or optical diffraction, thermionic emission, luminescence or acoustics) in the DEPARTMENT of PHYSICS—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (March 29).

LECTURER or ASSISTANT LECTURER in STATISTICS—The Secretary, The Queen's University, Belfast, Northern Ireland (March 31).

LECTURER (with special research interests in genetics) in the DEPARTMENT of BOTANY—The Deputy Secretary, The University, Southampton (March 31).

RESEARCH ASSISTANT (honours graduate in agriculture, agricultural science or geography) in the DEPARTMENT of AGRICULTURE for work in connexion with the effects of shelter on physical environment, animal performance and behaviour—The Professor of Agriculture, University College of North Wales, Bangor, North Wales (March 31).

SOIL SURVEY OFFICER (male, with a first- or upper second-class honours degree in science) for the SOIL SURVEY OF SCOTLAND—The Secretary, Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen (March 31).

TURNER AND NEWELL RESEARCH FELLOWS in ENGINEERING, INORGANIC CHEMISTRY, PHYSICS and allied subjects—The Registrar, The University, Manchester 13 (March 31).

LECTURER (honours graduate with research or industrial experience) in BREWING SCIENCE in the DEPARTMENT of BREWING and BIOCHEMISTRY—The Secretary, Heriot-Watt University, Edinburgh (April 1).

UNIVERSITY LECTURER in HISTORY OF SCIENCE or PHILOSOPHY OF SCIENCE—Dr. M. A. Hoskin, Whipple Museum, University of Cambridge, Free School Lane, Cambridge (April 1).

HYDROBIOLOGIST (with a good degree in biology (preferably zoology) and research experience in hydrobiology) at the University of Malawi to conduct research on planktonic and benthic organisms in Lake Chilwa—The Inter-University Council, 33 Bedford Place, London, W.C.1 (April 3).

CHAIR OF PATHOLOGY at the Western Infirmary—The Secretary to the University Court, The University, Glasgow (April 5).

UNIVERSITY LECTURER and a UNIVERSITY ASSISTANT LECTURER in PURE MATHEMATICS—The Appointments Committee, Faculty of Mathematics, University of Cambridge, Silver Street, Cambridge (April 5).

PROFESSOR (with considerable experience in teaching and research and some administrative experience) in the DEPARTMENT of AGRICULTURAL ECONOMICS, University of Ibadan, Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (April 7).

THIRD CHAIR OF MATHEMATICS (in the field of numerical analysis)—The Secretary, Queen's College, Dundee (April 8).

LECTURER (with a degree in either medicine or science and preferably some teaching experience) in the DEPARTMENT of PHARMACOLOGY, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, April 10).

POSTDOCTORAL RESEARCH FELLOW (with the degree of Ph.D. or about to submit a Ph.D. thesis) in EXPERIMENTAL OR THEORETICAL PHYSICS—The Registrar, The University, Hull (April 10).

CHAIR OF PHARMACEUTICAL CHEMISTRY at Chelsea College of Science and Technology—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 11).

ASSISTANT LECTURER/LECTURER (graduate with research experience in any branch of electronic engineering) in ELECTRONIC ENGINEERING—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (April 12).

LECTURER (with a special interest in theoretical chemistry) in the DEPARTMENT of CHEMISTRY, University of Ibadan, Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (April 12).

LECTURER (with an honours degree in electrical engineering with professional, academic or research experience in one of the following: control systems, power, electronics or communications) in the DEPARTMENT of ELECTRICAL ENGINEERING, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, April 14).

ASSISTANT LIBRARIAN (graduate with qualifications in librarianship and preferably with experience in a scientific library) in the PHILOSOPHICAL LIBRARY (scientific periodicals) for duties which will include assisting in the co-ordination of library services within the University—The Secretary, Philosophical Library Committee, University of Cambridge, Bene't Street, Cambridge (April 15).

LECTURER (with good academic qualifications, experience in organic analytical chemistry, and preferably an interest in polymer or petroleum chemistry) in the DEPARTMENT of CHEMISTRY—The Secretary, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (April 15).

SENIOR LECTURER or LECTURER (applied mathematician and able to teach either analytical dynamics, wave mechanics, hydrodynamics, electromagnetic theory or relativity) in the DEPARTMENT of MATHEMATICS, University of Khartoum—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (April 17).

SENIOR LECTURER or LECTURER in the DEPARTMENT of PHYSICS, University of Khartoum—The Secretary, Inter-University Council, 33 Bedford Place, London, W.C.1 (April 19).

READER in SOCIOLOGY at the London School of Economics—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 20).

LECTURER in the DEPARTMENT of ORGANIC CHEMISTRY, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, April 30).

LECTURER in GENETICS (any field) at the University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, May 1).

DEMONSTRATORS or ASSISTANT LECTURERS in the DEPARTMENT of HUMAN BIOLOGY and ANATOMY (one post may be reserved for someone interested in research, with opportunities for working for a higher degree)—Prof. R. Barrer, The University, Sheffield.

EXPERIMENTAL OFFICER (electron microscopist, preferably with experience in the ultramicrotomy of biological materials) in the SCHOOL of TEXTILE INDUSTRIES—The Registrar, University of Bradford, Bradford 7, Yorkshire.

RESEARCH ASSISTANT (with a first degree in a biological science) in the DEPARTMENT of ZOOLOGY, to work on problems of cell behaviour in tissue culture—The Secretary, University College London, Gower Street, London, W.C.1.

TECHNICIAN (preferably with experience of haematology and/or bacteriology) in the DEPARTMENT of MEDICINE—The Assistant Secretary, The Royal Veterinary College, Royal College Street, London, N.W.1.

**TECHNICIAN** (with histological experience) to assist research on brain and reproductive function in the DEPARTMENT OF NEURO-ENDOCRINOLOGY—The Secretary, Institute of Psychology, The Maudsley Hospital, Denmark Hill, London, S.E.5.

**VIROLOGIST** (preferably with a doctorate and several years experience in virology) to undertake research on mechanisms of immunity to viral infections—Prof. L. H. Collier, Lister Institute of Preventive Medicine (University of London), Chelsea Bridge Road, London, S.W.1.

**INTERESTED IN LIGHT-SCATTERING AS AN  
APPROACH TO MOLECULAR CHARACTERIZATION?**

A free literature kit is now available which contains recent articles on unusual approaches to molecular studies performed with light-scattering instrumentation.

Also included are brochures featuring the latest light-scattering instruments manufactured by Phoenix and 24 pages of selected references on light-scattering. The bibliography lists 930 publications in 22 categories from aerosols to synthetic polymers. These articles, all written after 1945, were chosen for their contributions to the field of light-scattering generally and their value to the study of particular systems.

If you are interested in the light-scattering approach to molecular characterization, send for your free copy of this valuable and informative literature kit.

**Ultrasonic  
Absorption**

*An Introduction to the Theory of Sound  
Absorption and Dispersion in Gases, Liquids  
and Solids*

A. B. BHATIA

After the introductory chapters on sound propagation in an ideal fluid and in an ideal elastic solid, the book successively deals with the various physical mechanisms responsible for sound absorption in monotonic and polyatomic gases, in normal and associated liquids, and in solids. 1 plate, numerous text figures 85s net  
*Monographs on the Physics and Chemistry of Materials*

**An Introduction  
to Magneto-Fluid  
Mechanics**

V. C. A. FERRARO and  
C. PLUMPTON

The authors have aimed to lay emphasis on basic principles and the more general results so far obtained in the subject. The second edition includes a more extensive treatment of force-free fields, anisotropic propagation of hydro-magnetic waves, oblique hydro-magnetic shocks, stability problems, charged particle drifts, collisionless plasmas, and waves in plasmas. Second edition, 2 plates, numerous text figures 50s net (paper covers 25s net)

**The Memory System  
of the Brain**

J. Z. YOUNG

These Hitchcock Lectures explore the useful analogy that may be drawn between brain and computer. Both select correct responses in answer to changes around them. Animals analyse their surroundings and pass the important data to the brain, which reacts by use of memory circuits established by previous experience. Professor Young has developed his theories through work on the octopus. 32 text figures 28s net

**Atomism in England  
from Harriot  
to Newton**

ROBERT HUGH KARGON

The author traces the history of the introduction and spread of the atomic doctrine as a case study of the problems of the establishment of the new learning and its methodology. He includes studies of the theories and methods of Harriot, Bacon, Hobbes, Boyle and Newton, as well as of the lesser figures who were historically so important. 42s net

### APPOINTMENTS VACANT

#### UNIVERSITY OF GHANA

##### DEPARTMENT BIOCHEMISTRY, NUTRITION AND FOOD SCIENCE

Applications are invited for the following posts:

#### (1) LECTURESHIP or ASSISTANT LECTURESHIP IN BIOCHEMISTRY

Candidates must have good postgraduate qualifications. Research experience in one of the following fields: plant biochemistry, microbial biochemistry, enzymology or mammalian or avian biochemistry would be an advantage.

#### (2) LECTURESHIP or ASSISTANT LECTURESHIP IN FOOD SCIENCE

Candidates must have good postgraduate qualifications. Research experience in one of the following fields: storage of root crops, microbiology and biochemistry would be an advantage.

Salary scales: Lecturer, £1,360 by £60 to £1,780 by £90 to £2,320 to £2,400 per annum; Assistant Lecturer, £1,150 to £1,200 per annum (non-taxable inducement allowance of £240 per annum and £150 per annum for expatriate Lecturers and Assistant Lecturers, respectively).

Appointment normally four or six years in the first instance, but shorter periods of secondment will be considered.

Further particulars and forms of application should be obtained from the Assistant Registrar, Universities of Ghana Office, 15 Gordon Square, London, W.C.1, or the Registrar, University of Ghana, P.O. Box 25, Legon, Accra, Ghana with whom applications (six copies) should be lodged not later than April 7 1967. (1215)

#### UNIVERSITY OF OTAGO

##### DUNEDIN, NEW ZEALAND

#### TEACHING FELLOWS IN THE FACULTY OF SCIENCE

Applications are invited for Teaching Fellowships in departments of the Faculty of Science. Duties will include teaching and research, the latter normally being directed towards the degree of Ph.D. Stipend: Up to £900 per annum for three years. Applications for appointments to commence in February 1967 should be received by the Registrar of the University by October 15, 1966. In order that the suitability of candidates and their proposed field of research can properly be assessed, preliminary enquiries should be addressed to the appropriate Heads of Departments by about September 15, 1966. Applications for appointments to commence in mid-1967 should be received by May 15, 1967, and preliminary enquiries by about April 15, 1967.

Further particulars are available from the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or from the Registrar of the University. (1244)

#### THE NATIONAL TRUST AND THE QUEEN'S UNIVERSITY OF BELFAST

#### WARDEN/NATURALIST

The National Trust and the Queen's University of Belfast invite applications for the post of Warden/Naturalist at Dundrum, County Down, from April 1, 1967. The salary is £1,000 per annum and will be subject to periodic review. The successful applicant will be required to join the contributory pension scheme of the National Trust. The closing date for receipt of applications is March 18, 1967.

Application forms and further details may be obtained from the National Trust, 82 Dublin Road, Belfast 2. (1195)

## Scientific Civil Service

### MATHEMATICIANS AND MATHEMATICAL PHYSICISTS

Scientists are required for work of a fundamental or innovating nature in computing science, mathematical physics and computer-aided design in the Basic Techniques Division of the Royal Armament Research and Development Establishment which is expanding its mathematical branch. Publication of results and the gaining of advanced degrees is encouraged.

This large establishment provides rich interplay among basic sciences, engineering and environmental studies and has pioneered many important phases of technology having a strong influence on the civil economy. A digital computer has been used since 1954 and the Establishment has developed its own compatible second generation machine plus computer languages and appropriate techniques.

Posts available include:

**MATHEMATICIAN/COMPUTER** for language studies and techniques of manipulation for operational problems involving massive data complexes such as terrain and movement studies and information retrieval;

**MATHEMATICAL PHYSICIST** with a good understanding of materials sciences or the dynamics of media and structures, particularly under impulsive loading. Techniques of direct simulation on analogue and digital machines will be as important as those of classical mathematical physics;

**MATHEMATICIAN** with engineering interests for the computer aided design of weapons, machines and instruments, with advanced technological content, for use in a wide range of environments.

Appointments are in the grades of Senior Scientific Officer and Scientific Officer, depending on age and experience. Superannuation initially under F.S.S.U. with opportunities for permanent Civil Service appointments with non-contributory pension scheme.

For further information please write to:  
The Director, Royal Armament Research and Development Establishment, Fort Halstead, Near Sevenoaks, Kent.

### MINISTRY OF AGRICULTURE, FISHERIES AND FOOD

Vacancies for SCIENTIFIC OFFICERS/SENIOR SCIENTIFIC OFFICERS exist as follows:

(i) One post at **Food Standard, Science and Safety Division, London**, to take charge of section dealing with information and liaison in Food Science and Technology. Experience in food industry information problems an advantage.

**QUALIFICATIONS** (see below) in science, preferably chemistry, microbiology or food science or similar qualification.

(Reference: S/52-53/MAFF2.)

(ii) One post at **Radiobiological Laboratory, Lowestoft**, suitable for graduate Zoologist with **Physiological/Biochemical Research** experience interested in problems related to metabolism of radionuclides in aquatic organisms; their internal movement at organ, tissue cell, and cell component level, with implication for internal dose and public health problems. Successful candidate will be part of team engaged on research and monitoring problems associated with radioactive waste disposal to aquatic environments. Further information from the Director, Dr. H. A. Cole, Fisheries Laboratory, Lowestoft. (Reference: S/52-53/MAFF3.)

Promotion prospects. Non-contributory pension.

**APPLICATION FORMS** from the Civil Service Commission, Savile Row, London W.1, quoting appropriate reference. Early application advised.

#### SALARIES, QUALIFICATIONS and AGE LIMITS

##### SCIENTIFIC OFFICER/SENIOR SCIENTIFIC OFFICER

**SALARIES:** S.O. £926-£1,574. (Increments and special £120 award for approved post-graduate experience.)

S.S.O. £1,744-£2,155. (Starting salary may be above minimum.) Most Scientific Officer Class appointments carry promotion prospects to Principal Scientific Officer: £2,250-£3,107. Salaries are supplemented in the London area.

##### QUALIFICATIONS:

S.O. 1st or 2nd class hon. degree or Dip. Tech. or equivalent or higher qualifications in appropriate subject. Age under 29.

S.S.O. As above plus at least 3 years' post-graduate research. Age normally 26-31.

A free booklet entitled **THE SCIENTIFIC CIVIL SERVICE** is available on request from Civil Service Commission, Savile Row, London W.1.

(1242)

## MORE PLACES TO FILL

NOBODY should be surprised that British universities have once more failed to fill all their vacant places in science and applied science (see page 1165). It has been clear for the best part of five years that the rapid expansion of departments of science and technology in the late fifties would be difficult to sustain indefinitely. Certainly nothing has happened in the last year or so to halt the slow drift away from science, or even to suggest what the root causes may be. The interim report of the Dainton sub-committee of the Council for Scientific Policy, now nearly a year old, served chiefly as another reminder that the problem remains unsolved. In the circumstances it is important to recognize that things could well be worse, but that the vacancies are not a problem in their own right but, rather, consequences of deep-seated tensions in the British educational system. Obviously there can be no quick solution.

The supposed drift away from the sciences is, in the first place, strictly relative. Admissions of potential scientists to British universities increased by 40 per cent in the five years from 1962. In the same period, admissions to courses in technology increased by 28 per cent. In strictly numerical terms, the universities should therefore be turning out steadily increasing numbers of graduates in science and technology in the years ahead. But the output of graduates in other faculties is likely to increase still faster. In the past five years the overall rate of admissions to universities has increased by 54 per cent, and has thus more than kept pace with the projections of the Robbins Commission. At the same time, however, admissions to courses in the social sciences have increased by nearly 120 per cent. This remarkable growth of interest by undergraduates in the social sciences is numerically just enough to explain why admissions in science and technology declined from 46 per cent of the total in 1962 to 40.6 per cent in 1966. It is also consistent with the recent popularity among senior students at schools of subjects such as economics. Another sign of the same tendency is the growing entry to the school-leaving examinations at advanced level of students with patterns of study which bridge whatever gap there may be between science and the humanities. The last report of the Universities Central Council on Admissions suggests that the numbers of sixth-formers following courses like these increased by 89 per cent between 1962 and 1966—far more quickly than the school population as a whole. Although there is nothing which can be called a stampede away from science and technology, the signs of disaffection are so consistent that there is obviously a real phenomenon to be dealt with.

What, then, should be done? The first thing to be said is that it would be inconsistent for a nation which spends a good deal of its time worrying about the loss of scientists and engineers by emigration, and about the tendency of skilled people to stay in academic life rather than to find their way into industry, unthinkingly to lament what seems to be a failure of school-leavers to become scientists. And it is entirely possible that the reasons why trained scientists tend to emigrate or to stay in universities, whatever they may be, may be linked in some way with a tendency for school-leavers to fight shy of science courses. The three phenomena would certainly be expected to follow naturally from a state of affairs in which there was a surplus of scientists, defined in the strictly economic sense that the demand is less than the supply. It is true, of course, that there are good reasons for believing that British industry would profit enormously from a much fuller use of scientific people, but that is only another way of saying that the demand for scientists is now lower than it should be. In other words, there is good reason to expect that a great many problems would be simplified if there were a general improvement of the conditions under which scientists and technologists are expected to work, particularly in industry. Nobody should be surprised if young people leaving school are hard-headed enough to know on which side their bread is buttered.

In the competition for school-leavers, numbers are not everything. Quality also matters, and there are signs that science departments at British universities are less able to recruit bright undergraduates. Certainly the UCCA report shows that science departments were having to accept as entrants students whose attainment, on paper at least, is hardly spectacular. In the humanities, on the other hand, students are being turned away with qualifications which indicate considerable ability. This feature of the balance between university entrants in various disciplines is in part, of course, a consequence of the numerical shortage of suitable entrants, but it is also clear that the science departments would do better if the curriculum were more flexible—and more interesting—at school and at university. The way in which sixth-formers are required to specialize in one set of subjects or another is absurd and damaging as well. To the extent that university departments insist that studies at school should be a narrow preparation for what happens at university, they are slowly cutting their own throats. The tendency for students at British schools to follow courses with one foot in science and one in the humanities is not an accident but a rebellion. In the long run, the universities would benefit if there were a more

liberal education in the sixth form. But university curricula are also much in need of being made more liberal. Courses which combine studies such as engineering and economics should be much more common than they are, for example. And the style of teaching in many departments could well be made more stimulating (and more educative) by borrowing from the schools some of the innovations which have recently transformed the teaching of science. In other words, although the most important reasons for the drift from science are probably beyond the reach of the universities, they could do a lot to help themselves.

## LABORATORY PEOPLE

THE White House panel on the conflict between personal privacy and the needs of scientific research has started some interesting hares (see page 1165). Although most of its recommendations are at once moderate and sensible, the issues of principle involved are bound to be contentious where they are taken seriously. Historically, the panel has its roots in exercises such as those in which groups of people were locked in air-raid shelters for days on end, and in which their conversation was recorded, allegedly unknowingly. The chances are that tactless investigations like those, whose claim to the title "experiment" is dubious to say the best of it, will not lightly be undertaken in future, but the panel is right to insist that the question remains of what rules should govern the relationship between biologists and the public. In one sense, of course, the question is as old as the hills, for there have always been doctors and doctors have always been doing things for the first time. But the arrival on the scene of great numbers of experimental biologists, with no written code of ethics nor great body of precedent as a guide, is a real complication.

The most obvious difficulty is that there can be no simple code of ethics. In the treatment of laboratory people, as of laboratory animals, the only general rule is that experiments should be designed so as to minimize pain, intrusion and other offences against the animal—human or otherwise. When unpleasantness seems unavoidable, an honest attempt must be made to balance this against such benefit as there may be. Often it will seem best not to carry out the experiment. But things will not always turn out as easily as this. Where people are concerned, the fact that they can be asked for their consent is a great help, but the committee is right to ask that they should be given a full understanding of what is involved. Whether the committee is right to ask grant-giving bodies to censor proposals is another matter. Institutions—and journals—are much more able to act objectively.

## ENERGY FROM WHERE?

THE British government is about to make a muddle of its fuel policy. Ever since natural gas was discovered

in the North Sea more than a year ago, the Ministry of Power has found it hard to suppress its excitement at the consequences. Naturally enough, the ministry is aware of how natural gas has transformed the economy of the Netherlands in the last two decades, and of how liberal supplies of it are an essential part of the economy of the United States. Indeed, it has probably not forgotten that the discovery of coal in Britain, and the development of techniques for mining coal, was the foundation for the great upsurge in British productivity nearly two centuries ago. It is understandable, then, that the steady pace of the discovery of gas wells in the North Sea has occasionally gone to the ministry's head. The trouble, unfortunately, is that the discoveries of gas coincided with the point at which nuclear power stations have become decisively cheaper than conventional power stations. If it were not for the gas, the ministry would no doubt be cock-a-hoop about nuclear power instead. But as recently as two years ago the British government also committed itself to the coal industry by letting Lord Robens feel that a reduction of coal production to about 170 million tons a year would be about the limit of the sacrifice expected of him in the interests of cheaper energy production. In the circumstances, it is no wonder that the Ministry of Power is torn between different and alternative sources of energy. Things have changed a lot since the fifties, when one report after another foretold great scarcity. What is the government to do?

In the first place, on gas, it would be a great benefit if the minister could restrain his enthusiasm and also the Gas Council. The production of the North Sea gas field may well turn out to be as great as the optimists forecast, but it does not follow that it is most economical to exploit it quickly. Indeed, the rapid conversion of existing plant from coal gas to natural gas upon which the Gas Council has embarked may in the long run turn out to be exceedingly wasteful of resources. To begin with, at least, it would probably have been more economic to use natural gas for providing big industrial consumers with gas supplies. Even power stations might have come high on the list of potentially good customers, even though the Gas Council has set its face against such a development. As things are, and whatever the outcome of the negotiations on the price for North Sea gas, the gas will be used chiefly in supplying customers for whom distribution costs are in any case much higher than the cost of gas, so that the economic benefit will be marginal—and imperceptible.

On nuclear power, the government's policy is most of all deficient in its passivity—a strange contrast with the involvement of the fifties, when the utility undertakings were overridden by the government and were required to build nuclear capacity that they did not want. Now the government appears to be letting events take their course, which means in practice that the comparatively high initial cost of nuclear power stations is tending to reduce the pace at which nuclear power is exploited. The most urgent need may now be to persuade the minister to transfer a part of his enthusiasm for gas to nuclear power.

## NEWS AND VIEWS

### Swings and Roundabouts

THE swing away from science gets another push in the fourth report of the Universities' Central Council on Admissions (UCCA, 29 Tavistock Square, London, W.C.1, 6s.). The end of the bulge in post-war births seems to have been a sharper shock in science and technology than in other disciplines. Last year there were more places at British universities for undergraduate scientists than there were applicants qualified to take them up; it has become significantly harder to get a place in the humanities than in the sciences. Pure scientists, who make up 19.2 per cent of all applicants, gain 26.2 per cent of the places, while social scientists make up 29.7 per cent of the applicants and get only 22.5 per cent of the places. The council demonstrates that the situation exists and goes to some lengths to translate it into figures. Last year there were, it says, 500 too few applicants in technology, and 1,100 too few in science, figures open to all sorts of criticisms. The council produces no evidence, for example, that the projections made by the universities of the number of places available are consistent from department to department. This is important because scientific departments gain much more from expansion than others do and as a result their optimistic predictions are less likely to be met.

For all that, the trend is convincing and, as the report notes, disturbing. Since 1962, admissions in pure science have grown by 41 per cent, in technology by 28 per cent, in arts subjects by 55 per cent, and in social studies (economics, sociology, psychology, law, geography) by no less than 118 per cent. Chary of falling off the fence, the council is content to record the figures and leave others to argue about them. It would be fascinating to learn, for example, where the shortfall is concentrated—well known and respected departments claim to have no difficulty in filling their places—and it may be that students are helping to create centres of excellence willy nilly by voting with their feet. The council bases its judgments on the premise that university entrance should be exactly as easy for arts undergraduates as for scientists. It might well be argued, though, that the hurdles to entry should be lower for scientists, as an encouragement. Perhaps, indeed, the shortfall should be welcomed for the effect it will have on the generation now in the schools.

### No Unwarrantable Intrusion

A WARNING that research into human behaviour may sometimes imply an unwarrantable interference with the privacy of people, and a code of values for the protection of individual privacy, are spelled out in a report of a panel under Dr. Kenneth E. Clark, chairman of the College of Arts and Sciences at the University of Rochester, and now published by the Office of Science and Technology in Washington (*Privacy and Behavioral Research*, U.S. Government Printing Office, 15c.).

The report says that the panel began work because of the threat to individual privacy implied by wire-tapping, electronic eavesdropping and similar innovations. On a number of occasions recently, the possibility that scientific enquiry might similarly intrude on personal matters has been raised in the United States Congress. While rejecting any notion that the 35,000 scientists who at present spend the \$300 million a year which the federal government devotes to behavioural sciences may be unaware of these problems, the panel does admit to having discovered a "limited number" of investigations in which privacy has been invaded.

The panel concludes that participation of experimental subjects in investigations must be voluntary and based where possible on "informed consent". Experiments should be designed in such a way that there is no permanent physical or psychological harm to participants. Similarly, published reports of research must protect the privacy of individuals, and government agencies supporting research should "satisfy themselves that the institution which employs the investigator has effectively accepted its responsibility to require that he meet ethical standards". Legislation, says the committee, is not necessary.

To the extent that these recommendations imply the supervision of the character of a person's work by his institution, they will in themselves be of some importance. In practice, the committee's interpretation of what is meant by privacy will raise other issues. As an example of intrusion, it cites an attempt at a sociometric measure in which children are asked questions designed to reveal their relationship to other children in the class. The committee says that this invades privacy because "it forces children to think about certain qualities of behaviour shown by one another and to reach firm conclusions about what is best or worst". The panel points out that in an experiment in which experimental subjects are given a sense of failure, the experimenter has a duty to see that they leave the laboratory with their natural spirits restored.

### New Fellows

THE Royal Society has broken new ground by the election of a number of technologists to the fellowship. The list of elections of March 16 includes eight people whose present work is more in industry than in academic life. The inclusion of technologists in the fellowship, not an entirely novel idea, has been given especial importance in the last few years, and Professor P. M. S. Blackett, the president, drew attention to the virtues of electing industrial people to the fellowship in his presidential address on November 30, 1966. Many of those now elected as technologists have distinguished records in pure research as well. The list of elections on March 16 is the following:

E. J. W. Barrington, Professor of Zoology, University of Nottingham; K. L. Blaxter, Director of the Rowett Research Institute, Aberdeen; E. S. Booth, Member for Engineering of the Central Electricity Generating Board; C. W. Bunn, Dewar Research Fellow of the Royal Institution; C. S. Cockerell, Consultant, Hovercraft Development Limited, and Chairman, Ripplecraft Limited, Southampton; J. V. Dacie, Professor of Haematology, Postgraduate Medical School, London; N. A. de Bruyne, Managing Director,

Techne Limited, Duxford; F. J. Dent, Director of the Midland Research Station of the Gas Council, Solihull; C. A. Fleming, Chief Palaeontologist, Geological Survey of New Zealand; H. Ford, Professor of Applied Mechanics, Imperial College of Science and Technology; S. D. Garrett, Reader in Mycology, University of Cambridge; M. A. Grace, Nuclear Physics Laboratory, University of Oxford; E. J. Hanson, Medical Research Council, Biophysics Research Unit, King's College, London; A. A. C. Issigonis, Technical Director of the British Motor Corporation, Birmingham; F. E. Jones, Managing Director, Mullard Ltd.; R. U. Lemieux, Professor of Organic Chemistry, University of Alberta; I. Maddock, Controller, Ministry of Technology; N. A. Mitchison, Head of the Division of Experimental Biology, National Institute for Medical Research; J. A. C. Nicol, Plymouth Laboratory, Marine Biological Association; D. C. Phillips, Professor of Molecular Biophysics, University of Oxford; C. H. B. Priestley, Chief, Division of Meteorological Physics, Commonwealth Scientific and Industrial Research Organization; C. R. Rao, Professor of Theoretical Statistics, Calcutta; R. Riley, Plant Breeding Institute, Cambridge; M. J. Seaton, Professor of Physics, University College, London; N. Sheppard, Professor of Chemistry, University of East Anglia; D. H. Smyth, Professor of Physiology, University of Sheffield; F. Sondheimer, University of Cambridge; H. P. F. Swinnerton-Dyer, Trinity College, Cambridge; D. F. Waterhouse, Chief, Division of Entomology, Commonwealth Scientific and Industrial Research Organization; A. Williams, Professor of Geology, Belfast; R. T. Williams, Professor of Biochemistry, St. Mary's Hospital Medical School, London; J. M. Ziman, Professor of Theoretical Physics, Bristol.

## Automatic Medicine

THE varied display of equipment at the International Medical Engineering and Automation Exhibition in London last week was a measure of the extent to which the engineers are now moving in on the medical field. Medical research, even in Britain, seems to have left string and sealing wax firmly behind, and the hospitals are also taking advantage of the new methods and techniques. One popular exhibit at Medea 67 was the use of fibre light guides in such instruments as the gastroscope developed by the Atomic Weapons Research Establishment of the U.K. Atomic Energy Authority. The same principles are also being used in an instrument which can be passed into a blood-vessel to show the colour of the walls and contents, and which can thus be used to localize blood clots. Cardiac pacemakers, shown by a number of manufacturers, are typical of the miniaturized equipment now coming into service. Some of the pacemakers on show could perform such tricks as altering their pace automatically when the patient is exercising and even switching on only when the heart stops. Dialysis machines were much in evidence, and several manufacturers had something useful to show.

## Keeping Fruit

SOME of the farmers who attended the open day of the East Malling Research Station on Wednesday, March

15, may have needed to be reassured about the value of continuing with the research on fruit storage going on at the station. If this was so, and Dr. H. B. S. Montgomery, assistant to the director, seemed to think so when he spoke to the large group of fruit growers at the station, it is not because the research carried out so far has been a failure. The research team in the pomology unit has been able to define the conditions of storage best suited to the different types of apples and to the different requirements of the grower. It has also made some progress in finding the causes of the gradual decline in the quality of apples stored for some time. All this research has been valuable in direct cash terms to the growers, who have supported the study by sending samples of their fruit to the laboratory for study. Because of the improvement of fruit storage resulting from the work of the laboratory, farmers no longer have to rush to market with their produce the moment it has been harvested. By a quirk of economics the results benefit not only the farmers who invest in the complex machinery required for the new methods of storage, but also those who do not have any special equipment. This may have produced some feeling that research into storage methods is not really worthwhile. The research staff at the station considers, however, that it has captured the enthusiasm of farmers up and down the country and that, if it asks, it will continue to get help from these farmers.

The station is also expanding the more general aspects of its research. A new electron microscope has just been installed to be used for studies of plant viruses and the fine structure of plant cells. It will have to turn to more fundamental studies of plant parasites because the experimental farm has swallowed up all the available land in the area around the laboratory.

## Maps by Machine

MAPS as a means of displaying information have been caught up in what is known as the information explosion. Partly this is because the amount of information available to map makers has increased at enormous speed since the introduction of automatic data collection and logging; the next step logically seems to be automatic map drawing by computer. A one day discussion meeting on the subject of automated cartography was held on March 20 by the joint computer groups of the Institution of Electrical Engineers, the Institution of Electronic and Radio Engineers, and the British National Committee for Geography of the Royal Society.

Mr. D. P. Bickmore of the Clarendon Press at Oxford defined the need. "The first—and urgent—need is to reconstitute an existing map from digital information, automatically, and so that it conforms to traditional standards of appearance and accuracy. This will show how much hand work is still necessary, and what modifications in style, information or even accuracy should be considered". Forms of output other than lithographic printing on paper must be considered, he said; high speed plotters or cathode ray tubes may give a quick preliminary look at a map. Professor D. Linton of the University of Birmingham pointed out that only a tiny proportion of the mass of demographic and climatic information collected by governments ever sees print in map form. Information is simply

tabulated by area, and the possibility of spotting regularities or correlations—say the incidence of pellagra, family expenditure on food, and the provision of medical services in the eastern United States—is very remote indeed. Such interesting relations as have been found are the result of years of searching, and merely increase the sense of frustration that there is no better way of doing it. Other speakers, from the General Register Office, the Ordnance Survey, and the Meteorological Office, discussed their own approaches to the problem. As Mr. Bickmore sadly admitted, nothing so far qualifying as a real map has been produced automatically in Britain or in the United States. He was hopeful, though, that something would be done before the end of this year.

## Reactors at Sea

THE economics of marine propulsion by nuclear reactor have been derided so often—most recently by Sir William Penney, Chairman of the Atomic Energy Authority—that believers need either considerable courage or blind optimism. Despite the figures recently issued for the U.S.S. *Savannah*, the United States nuclear ship, which requires an operating subsidy of close on a million dollars a year, and will cease to operate when the subsidy runs out, Mr. J. A. Teasdale, lecturer in Naval Architecture and Shipbuilding at the University of Newcastle upon Tyne, believes that a competitive nuclear powered nuclear ship could be built. In a paper read before the Royal Institution of Naval Architects on March 22, he described his design.

The ship would be in two parts, one containing the motive power and the other the cargo holds. The chief advantage would be to make full use of the expensive machinery in the motive part of the ship by doing away with long periods of idleness during loading and unloading. On delivery of a cargo, the pusher section would separate itself and depart almost immediately with another cargo unit which had been loaded in readiness. For the same power source, Mr. Teasdale claims that this concept would have both lower capital and running costs than an equivalent number of conventional ships. The design could of course be used with normal power sources, but since nuclear power plant would not require large oil storage tanks some of the difficulties in matching draught and trims would be removed.

The joint between the two sections should be either flexible or completely rigid. The flexible design would have to accommodate large forces in several degrees of freedom, and it is probable that the rigid design would be preferable. For the actual link, Mr. Teasdale visualizes a ratchet arrangement with a V-shaped bow for the pusher unit and a corresponding recess in the cargo unit. After positioning the pusher unit correctly, water ballast would be taken on to engage the ratchet. To get the best advantage from the design, the voyage time should be equal to half of the loading or discharging time of the cargo. A suitable route, Mr. Teasdale suggests, would be Liverpool–New York, at a service speed of 21 knots. One pusher unit and three cargo units, he says, would be equivalent in handling capacity to 2.43 conventional ships. After what he admits to be an elementary cost comparison, he concludes that a nuclear composite ship could be competitive with existing vessels. Using the design with a diesel main engine

would, he thinks, lead to “considerable savings in cost”.

## High Powered Co-operation

THE Cavendish Laboratory at Cambridge, the Ministry of Technology and Associated Electrical Industries, Ltd., are all agreed that there are substantial scientific and economic gains to be had from the development of high voltage electron microscopes. Dr. V. E. Cosslett at the Cavendish has designed and built a microscope operating at 750,000 volts, and AEI has decided to build the microscope, scaled up to 1 million volts and with minor design modifications, and to sell it commercially for a price in the region of £180,000. Where the ministry comes in nobody is quite sure, but it is on the scene and beside itself with pleasure at this example of collaboration between industry and the university.

In order to build the microscope at Cambridge, some structural alterations were necessary at the Cavendish; a students' laboratory was annexed for the electron accelerator, a large hole made in the floor, and the actual microscope sited in the cellar below, previously a battery room. The microscope is beautifully engineered, about twice as large as conventional ones, and has been in use for a year. Results have been very encouraging, and it seems that some of the doubts expressed about high voltage microscopes were unjustified. Apart from the opportunity to use much thicker specimens in transmission, there has been a considerable improvement in clarity, and fine detail invisible at 250 kV can be seen at 750 kV. For biological specimens damage is less than at 100 kV, perhaps surprisingly, and for metallurgical work the interpretation of the electron micrographs is not unduly complicated by the increase in thickness; the use of stereo pictures can help. The microscope has the advantage of operating over the whole range from 100 kV to 750 kV, and AEI intends to preserve this feature when it puts the design into production.

So far, the microscope has been used, among other things, for the examination of wool fibres, porcupine quills and membranes for artificial kidney machines, but the obvious application is in metallurgy. Foils

Fig. 1. Domains in a wedge-shaped cobalt foil, photographed by Lorentz microscopy in the Cavendish Laboratory microscope. Voltage 700 kV, magnification about 5,000. (P. J. Grundy and J. P. Jakubovics, Cavendish Laboratory.)

up to  $1.4\mu$  thick can be examined, and the instrument already has one triumph behind it—the identification of an alloy inclusion which would have fallen out if conventional thinning techniques had been needed. AEI is confident that a number of 1 MV microscopes can be sold, and has orders from the National Physical Laboratory, the Atomic Energy Authority at Harwell, and the Science Research Council. Deliveries will start in two years time, which gives some Japanese companies a substantial lead—they are already marketing 500 kV and 1 MV instruments. In France and the United States the talk is now in terms of 3 MV and 5 MV instruments.

## Select Committee

THE Select Committee on Science and Technology continued its search for something to be shocked about when it discussed the British nuclear reactor programme with a delegation from the Central Electricity Generating Board on March 16. In earlier discussions, Sir William Penney had suggested that substantial savings could be made by using standardized designs, but Mr. F. H. S. Brown, chairman of the CEBG, did not agree. He thinks that greater savings can be made by technological development than are possible by replication of design. While standardization could doubtless give a price reduction of 7–10 per cent, development had brought down the cost of reactors from £180 a kW for the "Magnox" reactor to £100 a kW for the Advanced Gas Cooled reactor. Standardization in the United States, Mr. Brown believes, has only been possible because water moderated reactors are at the end of their development. To give up development of the AGR for the sake of marginal cost reductions would be foolish.

Mr. Brown went on to give the committee the following comparison of the costs of two AGR power stations and one new coal fired power station.

	Capital costs (per kW)	Running costs (d/kWh)
Dungeness B	£104.8	0.511
Hinkley Point B	£95.5	0.476
Drax (coal fired)	£55.2	0.577

During its proceedings last week the committee did finally sight a hare to chase. Apparently the capital expenditure of the CEBG for the financial year that begins at the end of March has not yet been approved by the Ministry of Power. Some members of the committee were clearly taken aback although the CEBG patiently explained that it would make very little difference as long as capital projects already under way would not have to be brought to a shuddering halt. This had not happened, although the start of the Hinkley Point B station had had to be delayed by 12 months, and the CEBG would therefore have to wait another year before reaping the economic advantages of the new station. As for natural gas, the men from the electricity industry would not be drawn—they would, of course, be well placed to use the gas for electricity generation, but all depended on the price fixed for the gas. Was the Ministry of Power influenced by greedy thoughts of what natural gas could do for British power generation? Did this make it reluctant to approve new expenditure on nuclear plant? On their best behaviour, the CEBG delegation refused to guess.

## Parliament in Britain

REPLYING to a request for a statement on the future of the National Reference Library of Science and Invention, the Minister of State at the Department of Education and Science, Miss Jennie Lee, said in the House of Commons on March 13 that the provision of a new building was a matter for the Minister of Public Building and Works. A working party representing the British Museum, the Treasury, the Ministry of Public Building and Works and the Department of Education and Science was reviewing the space required. The 1966 report of the Trustees of the British Museum revealed encouraging progress in staffing, acquisitions, physical reconstruction and improvement, and the next few years should see considerable further developments.

In a written answer in the House of Commons on March 14, the Secretary of State for Commonwealth Affairs, Mr. H. Bowden, stated that the Government had under consideration the recommendation of the mission under the chairmanship of Sir Charles Morris (now Lord) that a comprehensive university institution to serve the needs of the English speaking territories in the South Pacific area should be established at Laucala Bay, Fiji. Mr. Bowden said that the British Government would be prepared to offer, subject to approval of Parliament, £1.25 million sterling over some 5 years towards the initial cost of the university, including related institutes, of which up to £500,000 could, if necessary, be devoted to recurrent costs. The provision of assistance is subject to a firm decision by the Fiji Government, after such consultation as it may find necessary with other governments in the area, to proceed with the establishment of the university. The New Zealand Government has already promised help.

On March 15 the Postmaster General, Mr. E. Short, told the House of Commons that in the past year the Post Office had earned 7.8 per cent overall on capital compared with a target of 8 per cent and the predicted return for 1967–68 was 7.4 per cent. Over the whole five year period it was anticipated the return on the postal side would be short of the target, but not on the telecommunications side. Much postal work offered little or no scope for increased mechanization, about 40 per cent of postal costs being incurred in collecting and delivering mail, and the profit of £4 million this year was made on an income and expenditure of about £340 million. Subscriber trunk dialling (STD) was now available on about three-quarters of the telephones in Britain and by the end of 1967 fewer than 3 per cent of subscribers would be connected to manual exchanges. There would be none after 1970–71.

MR. SHORT said that the number of staff trained in the latest management techniques of work study and operational research was being increased; about £4 million worth of computers were already installed and working; others to the value of £3 million were on order, and by 1971, 20 large computers would be in operation. It was expected that in about 2 years time use of computers in telephone accounting would save over 2,500 clerical staff, and in posts and telecommunications was expected to save over 12,000 staff in the next few years.

## University News:

## London

THE following appointments to chairs have been made: Dr. J. L. Hancock, a member of the A.R.C. Animal Research Organization, to the chair of anatomy tenable at the Royal Veterinary College; Sir Francis Knowles, professor of comparative endocrinology in the University of Birmingham, to the chair of anatomy tenable at King's College; Dr. E. Leader, research fellow at Clare College, Cambridge, to the chair of theoretical physics tenable at Westfield College; Dr. I. W. Roxburg, reader in astronomy in the University of Sussex, to the chair of applied mathematics tenable at Queen Mary College.

Sir Hans Krebs, Whitley professor of biochemistry in the University of Oxford, has been appointed as visiting professor of biochemistry in the Royal Free Hospital School of Medicine, a position he will continue to hold after his retirement from the Oxford chair. This is the first appointment in a new scheme the school has adopted for the appointment as visiting professors of men and women, from other academic or research institutions or from government departments, industry or commerce, who are distinguished in the fields of medicine and science allied to medicine.

## Announcements

THE International Agency for Research on Cancer is awarding travel fellowships during 1967-68. The fellowships are intended to provide opportunities for visits to other laboratories for consultation, collaborative planning of research projects, and the acquisition and standardization of new research techniques, and applicants must be actively engaged in cancer research and qualified in natural or medical sciences. The Agency is also awarding research training fellowships in 1968 and applications are invited from junior scientists wishing to be trained in any aspect of cancer research, including epidemiology and biostatistics. Applicants should preferably be already engaged in research in medical or allied sciences and intend to pursue a career in cancer research. Further information concerning both fellowships can be obtained from the Chief of the Education and Fellowships Programme, International Agency for Research on Cancer, 16 avenue Maréchal-Foch, 69-Lyon (6e).

PROFESSOR J. GRAHAME CLARK, Disney professor of archaeology in the University of Cambridge, has been awarded the Hodgkins gold medal by the Smithsonian Institution. This medal, which is accompanied by a \$3,000 honorarium, is awarded periodically for important contributions to knowledge of the physical environment bearing on the welfare of man.

THE 1966 Prince Philip Medal for outstanding promise or achievement in the promotion, theory or practice of science or technology has been awarded to J. B. Warman, departmental chief engineer, Telecommunications Division, Associated Electrical Industries Ltd.

THE James Watt International Medal has been awarded by the Institution of Mechanical Engineers to Professor I. I. Artobolevskii, a member of the Academy of Sciences of the U.S.S.R., in recognition of his contributions to mechanical engineering, particularly in the field of mechanisms.

THE 1967 Coblentz Society Award has been presented to Professor P. J. Krueger, professor of chemistry and chairman of the Department of Chemistry in the University of Calgary, in recognition of his contribution to the field of infra-red spectroscopy.

A SHORT course on "Mechanical Design" is to be held in the University of Bradford during May 1-5. Further information can be obtained from the Registrar, University of Bradford, Bradford 7.

CIBA Laboratories, Ltd., Horsham, have donated, initially for a period of seven years, a silver medal and prize of £50 to be awarded annually by the Biochemical Society for outstanding research in any branch of biochemistry. Nominations are now invited for the third award, which will be made in 1967, and further information can be obtained from the Executive Secretary, The Biochemical Society, 20 Park Crescent, London, W.1.

THE National Technical Committee of the Society of Instrument Technology is to set up a Study Group on automation in design for manufacturing processes. Further information can be obtained from the Society of Instrument Technology, 20 Peel Street, London, W.8.

A SECOND conference on "Static Electrification", arranged by the Institute of Physics and the Physical Society, will be held at the Institution of Electrical Engineers during May 8-10. Further information can be obtained from the Meetings Officer, The Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

AN international symposium on "Molecular Associations in Biology" will be held at the Institut de Biologie Physico-Chimique, Paris, during May 8-11, in celebration of the fortieth anniversary of the foundation of the institute. The main object of the symposium will be to discuss the principal forces involved in such associations, the means for their detection and the principal biological systems and problems in which they are in operation. Further information can be obtained from Professor B. Pullman, Institut de Biologie Physico-Chimique, 13 rue Pierre Curie, Paris 5e.

A SYMPOSIUM on "Composite Polymeric Materials" is to be held in the University of Bradford during May 12-13. Further information can be obtained from the Registrar, The University of Bradford, Bradford.

A SYMPOSIUM on "Diagnosis and Treatment of Deposited Radionuclides", sponsored by the Battelle Memorial Institute-Pacific Northwest Laboratory, Hanford Occupational Health Foundation, Inc., and the U.S. Atomic Energy Commission, is to be held in Richland during May 15-17. Further information can be obtained from Dr. J. F. Park, Symposium on Diagnosis and Treatment of Deposited Radionuclides, P.O. Box 999, Richland, Washington 99352.

A SECOND national symposium on radioecology entitled "Nuclear Energy in Man's Environment: Past, Present and Future Problems", sponsored by the Atomic Energy Commission, the Ecological Society of America, and the University of Michigan, will be held in the University of Michigan at Ann Arbor during May 15-17. Further information can be obtained from Dr. F. C. Evans, Department of Zoology, University of Michigan, Ann Arbor, Michigan.

AN international colloquium on "Solid Inorganic Phosphates" will be held in Toulouse during May 16-20. Further information can be obtained from the Secrétariat Général du Colloque International sur les Phosphates Minéraux Solides, 38 rue des Trente-Six Ponts, 31-Toulouse.

THE fifth international conference on "Non-Destructive Testing", sponsored by the Canadian Council for Non-Destructive Technology, will be held in Montreal during May 21-26. Further information can be obtained from the Secretary, The British National Committee for Non-Destructive Testing, Redfields Home Farmhouse, Church Crookham, Aldershot, Hants.

THE fourth international seminar on "Gel Permeation Chromatography" will be held in Florida during May 22-24. Further information can be obtained from the chairman

of the Fourth International Seminar, c/o Waters Associates, Inc., 61 Fountain Street, Framingham, Massachusetts 01701.

A CONFERENCE on "Frequency Generation and Control for Radio Systems" will be held at the Institution of Electrical Engineers during May 22-24. The aim of the conference is to review the developments in techniques of frequency generation, synthesis, control and distribution as applied to radio communications, navigation and radar systems. Further information can be obtained from the Conference Section, Institution of Electrical Engineers, Savoy Place, London, W.C.2.

AN international congress on "Sulphur Oxides" will be held in the University of Toulouse during May 22-26. Further information can be obtained from the Secrétariat du Congrès, Association des Ingénieurs du Génie Chimique, Institut du Génie Chimique, Chemin de la Loge-Emplot, 31-Toulouse.

**CORRIGENDUM.** In the article entitled "Activity of Ribosomal Phosphodiesterase in a Protozoan", by L. H. Lazarus and O. H. Scherbaum (*Nature*, 213, 887; 1967), the following should be added to the end of the last sentence of para. 5: ", either as magnesium and/or calcium ions.". Lines 10 and 11 of para. 6 should read: "... This ribosome-bound enzyme with its high pH for optimum activity is ...". In line 3 of the legend to Table 1 "magnesium chlorate" should read "magnesium chloride". The fifth line of the legend to Table 2 should be "... tryptophan plus potassium chloride relative to potassium chloride alone.". In the first column in Table 2 the word "Plus" should be deleted from entries 5-8. The last two entries in this column should then be moved under entry 8.

**ERRATUM.** In the article entitled "Preliminary Observation on the Lipids of Bovine Retinal Outer Segment Disks" by S. Fleischer and D. G. McConnell (*Nature*, 212,

1366; 1966), the second line of the third paragraph should read "resolved into six fractions. . . .".

**ERRATUM.** In the article "Reduction of Methaemoglobin in Haemoglobin Samples using Gel Filtration for Continuous Removal of Reaction Products" by H. B. F. Dixon and R. McIntosh (*Nature*, 213, 399; 1967), second paragraph, line 5, "12 mg sodium dithionite" was incorrectly given as "12 ml. . . .".

## CORRESPONDENCE

### Asbestos in the Lungs

SIR,—The first paragraph of this review (*Nature*, 213, 855; 1967) states that mesotheliomas of the pleura and peritoneum only occur in association with exposure to crocidolite asbestos dust. This statement is not in accordance with our present knowledge. These tumours have occurred in people in whom no evidence of exposure to asbestos dust was established. Furthermore, crocidolite is not necessarily the only type of asbestos implicated. Investigations in the United States<sup>1,2</sup> have indicated that other types of asbestos may be involved. The international investigations which are described later in your article are planned to measure the absolute and relative risk of tumour development with all types of fibres.

Yours, etc.,

# Morphological Conversion of Cells *in vitro* by *N*-Nitrosomethylurea

by

F. K. SANDERS  
BARBARA O. BURFORDVirus Research Unit,  
Medical Research Council Laboratories,  
Carshalton, Surrey

A system is described for investigating the primary events involved in the induction of tumours by certain chemical carcinogens. It is based on the finding that such compounds alter the mode of growth of cells from a Chinese hamster lung tissue cell line in culture, and that the effect accompanies an ability to cause tumours when such cells are later injected into foreign host animals.

WHEN intact animals are treated with tumour-inducing agents, tumours usually appear only after many weeks and often in places remote from the original site of carcinogen application. Because tumours may arise from one, or at most a few, altered cells, experiments of this kind provide little knowledge of the nature of the initial, irrevocable, interaction between a carcinogen and cells directly affected by it. Thus, most current hypotheses concerning the primal events of cancer induction draw their support from information regarding the behaviour of carcinogens under metabolism by cells and tissues in short-term biochemical experiments<sup>1</sup> and their interaction with cell constituents *in vitro*<sup>2</sup>. Recently<sup>3,4</sup>, after successful experiments with oncogenic viruses<sup>5,6</sup>, cells have been treated in tissue culture with chemical carcinogens in order to search for cell colonies which have been "transformed" morphologically, the constituent cells of which may have the ability to cause tumours when later transplanted into animals. Although success was achieved, carcinogenic hydrocarbons of proved efficacy in animal experiments, compounds of notoriously low solubility in aqueous media, were used, and left in contact with the treated cells for several cell generations. In one experiment<sup>3</sup>, the way in which the carcinogen was applied made it difficult to be certain how much of it actually reached the cells, and in the second study<sup>4</sup> failure to detect clear-cut morphological changes *in vitro* made it obligatory to test for cell conversion by transplanting the cultured cells into animals.

This article describes a system whereby cells from a single serially cultured clone of mammalian cells, treated only briefly with a carcinogen *in vitro*, acquired (a) a capacity for altered growth when cultured later, as well as (b) an ability to grow as tumours in a heterologous host. The compounds used are all soluble in water, and the rate of cellular conversion is very high. These facts suggest that the system may be valuable for further investigations of the primary events involved in the induction of tumours.

The cells used came from a pseudodiploid, male Chinese hamster lung tissue cell line, serially cultivable *in vitro* as monolayers on glass or plastic. They came from the same source as the agar-passage line used by Borenfreund *et al.*<sup>4</sup>, but had not been so adapted; they were obtained from the Sloan Kettering Institute, New York, in 1965. A large stock of cells kept frozen in 10 per cent dimethylsulphoxide at  $-70^{\circ}\text{C}$  was used throughout. Cells for experiments were obtained by sub-culture from this frozen stock, but were not used at a passage level more than fifty cell generations later than that of the frozen material. Experimental batches of cells were grown up in stoppered Roux flasks and babies' bottles in a medium consisting of Eagle's basal medium (Hanks salts), 10 per cent tryptose

phosphate broth and 10 per cent foetal calf serum<sup>7</sup>. Experiments, using the same medium, were conducted in 5 cm plastic Petri dishes, incubated at  $37^{\circ}\text{C}$  in a water-saturated atmosphere containing 5 per cent of carbon dioxide.

Three compounds were tested, all of them obtained from Dr. P. N. Magee: (i) *N*-nitrosomethylurea (NMU)—this is one of the most effective carcinogenic substances known, causing primary gastric cancer in rats after a single oral dose<sup>8</sup>; (ii) dimethylnitrosamine (DMN)—a powerful representative of a class of hepatotoxic substances, also capable of causing liver cancer in rats after

Fig. 1. Toxic effect of nitrosomethylurea (NMU), dimethylnitrosamine (DMN), or methylurea (MU), on the capacity of Chinese hamster cells to form colonies *in vitro*. The upper part contains the pooled results of three experiments with NMU. The lower part compares NMU with DMN and MU.

oral or intravenous administration<sup>9</sup>; (iii) 1-methylurea (MU)—chosen essentially as a non-toxic control.

All three compounds were used as a 1 mg/ml. solution in phosphate buffered saline (PBS), stored at +4° C in the dark. Trypsinized, washed cells were suspended in growth medium or PBS, the proper concentration of test substances added and the mixture incubated with gentle shaking at 37° C; after 2 h, or shorter times when the time necessary for carcinogen action was being investigated, the mixture was diluted and plated in one of two ways: (1) A volume estimated to contain 10<sup>5</sup> cells was plated in 5 ml. of liquid growth medium. After 14 days the number of colonies formed, and their morphology, was recorded. Under these conditions untreated cells had a plating efficiency of about 20 per cent. Alternatively, (2) 0.1 ml. of diluted incubation mixture containing 1–2 × 10<sup>4</sup> cells was plated in semi-solid agar<sup>10,11</sup>. The overlay contained 0.33 per cent washed agar, and under these conditions the plating efficiency of untreated cells was 5–10 per cent.

The ability of treated, as well as untreated, cells to grow as tumours was tested by injecting 0.1 ml. of culture medium containing 1 × 10<sup>6</sup>–1 × 10<sup>8</sup> cells into the cheek pouches of cortisone-treated (0.1 ml. cortisone acetate, 25 mg/ml., subcutaneously, twice weekly), 3–4 week old hamsters<sup>12</sup>. Cheek pouch nodules were removed after 10–20 days and prepared for histological examination as well as further investigation in tissue culture.

0.3–0.5 µg/ml. of either 7–12 dimethylbenzanthracene, 3-methylcholanthrene or 3.4 benzo(a)pyrene reduced the plating efficiency of Chinese hamster cells in agar by

up to 90 per cent<sup>4</sup>. The three compounds tested here were much less toxic. Fig. 1 shows that two of them, namely DMN and MU, were virtually non-toxic up to a concentration of 100 µg/ml. in liquid medium. NMU, at the same concentration, reduced the number of cells potentially capable of forming colonies by 85 per cent. A similar toxicity was found when cells were plated in agar. It should be remembered, however, that all three compounds were only allowed to act briefly before dilution of the mixture to a concentration below that at which any activity could be demonstrated. Any lack of toxicity compared with the hydrocarbons can then perhaps be ascribed to the short time during which they were allowed to act. With NMU a further factor may be the innate instability of this compound in biological media under the conditions used.

Cells treated with NMU at all concentrations greater than 10 µg/ml. grew into colonies which could easily be distinguished from their normal counterpart. The majority (more than 80 per cent) of the colonies given by the latter were flattened, up to five cells thick at the centre, but consisting peripherally of a broad monolayer the constituent cells of which exhibited a marked parallel orientation (Fig. 2a). The rest consisted either of small nests of epithelial cells or diffuse collections of small fibroblasts one cell thick, but nevertheless exhibiting an essentially parallel orientation. Most colonies from cells treated with NMU, however, had centres up to twenty cells thick; the periphery of such colonies tended to remain multilayered and the cells comprising them to grow over one another with a criss-cross orientation (Fig. 2b).

Epithelial and small fibroblastic colonies were present, but were also disordered as compared with their normal counterpart.

Up to seven passages, either of clones derived from single colonies, or mass populations obtained by trypsinization of plates containing up to a hundred colonies of cells treated with NMU, gave cultures consisting of colonies the morphology of which remained essentially as described. It is therefore clear that treatment with NMU causes cells to change their mode of growth *in vitro*, and that this change is hereditary, persisting through subsequent generations under conditions when significant quantities of the carcinogen can no longer be present. Plating, and sub-culture, of NMU-treated cells in agar did not give a similar result. Individual colonies were larger than those given by untreated cells but had essentially the same morphology.

Toxicity, and cell conversion, of a similar degree was found when NMU was allowed to interact with cells either in growth medium or in PBS; it would appear that simultaneous rapid cellular syntheses are not essential to the eventual expression of the NMU effect. Fig. 2b illustrates the morphology of colonies arising from cells treated with NMU.

In contrast to NMU, colonies of cells treated with DMN, at whatever concentration, exactly resembled those given by untreated cells, whether plated in liquid medium or in agar (Fig. 2c).

A surprising result followed the treatment of cells with MU. This substance, not so far listed as a carcinogen, gave rise in all concentrations exceeding 40 µg/ml. to altered colonies with a morphology like those found after treatment with NMU (Fig. 2d). When first found, it was thought that this effect was due to an impurity in the sample tested, but repetition

Fig. 2. Photographs, at the same magnification, of crystal violet-stained colonies of Chinese hamster cells, arising from: (a) untreated cells; (b) cells treated with 20 µg/ml. NMU; (c) cells treated with 80 µg/ml. DMN; (d) cells treated with 80 µg/ml. MU.

of the experiments with a re-crystallized sample of MU gave the same result over the same range of concentrations. Experiments are in progress involving further related compounds, in order to unravel the nature of this effect.

When cells treated *in vitro* were tested for their ability to grow *in vivo* by inoculation into the cheek pouch of Syrian hamsters, all cell populations derived from tissue culture colonies "converted" by NMU were able to grow in the alien host (Table 1). Untreated normal cells, or cells treated with DMN, failed to grow in the cheek pouch. It is as yet too early to know whether cells from different colonies vary in their ability to give rise to nodules in the cheek pouch or whether several alternating passages *in vitro* and *in vivo* are necessary to select a cell line with a high capacity to cause tumours when only a few cells are injected<sup>13</sup>.

Table 1. CHEEK POUCH NODULES IN SYRIAN HAMSTERS AFTER INOCULATION OF CHINESE HAMSTER CELLS

	Tumours after inoculation of $1 \times 10^6$ cells
Cells from untreated colonies	0/10
Cells from colonies after NMU treatment (10 $\mu\text{g}/\text{ml}$ )	5/10
Cells from colonies after NMU treatment (100 $\mu\text{g}/\text{ml}$ )	10/10
Cells from colonies after DMN treatment (80 $\mu\text{g}/\text{ml}$ )	0/10

An attempt was made, using NMU, to determine the minimum time of cell/carcinogen interaction necessary to ensure morphological conversion.  $1 \times 10^6$  cells/ml. preheated to  $37^\circ\text{C}$  were treated with 20  $\mu\text{g}/\text{ml}$ . NMU, the reaction stopped at intervals by five-hundred-fold dilution in medium chilled to  $4^\circ\text{C}$  and the samples plated in liquid medium. Fig. 3 shows that contact between cells and this concentration of NMU for only 1 h is sufficient to achieve conversion. This time is far shorter than the mean generation time of these cells ( $\geq 12$  h in our hands) and its significance in relation to intracellular events remains to be determined.

Cells treated *in vitro* with carcinogenic hydrocarbons, besides being capable of giving rise to tumours, are also able to grow in the presence of hydrocarbon concentrations which would otherwise be lethal<sup>3,4</sup>. This suggests that, with hydrocarbons, selection must play a part in the appearance of such cells, although, when rendered neoplastic by other means, such as virus infection, cells also resist high hydrocarbon concentrations<sup>14</sup>. It was therefore of interest to determine whether cells converted *in vitro* by NMU also became resistant to the toxic effects of this compound. Fig. 4 shows the result of an experiment in which the plating efficiencies of untreated cells, as well as cell populations grown up from colonies converted after treatment with 10  $\mu\text{g}/\text{ml}$ . and 100  $\mu\text{g}/\text{ml}$ . NMU, were compared after further treatment with various concentrations of NMU. The results suggest that NMU converted cells do not have an augmented resistance to this compound. The lack of acquired resistance, the marked effect of a brief treatment and the fact that a high proportion of converted colonies is found at rela-

tively non-toxic levels of NMU all suggest that the effect of NMU on the cells may well be a direct one, and not the selection of a previously existing cell type. It would thus be of particular interest to determine whether conversion of cells by NMU endows them with the ability to resist otherwise lethal concentrations of carcinogenic hydrocarbons.

Fig. 4. Resistance of the colony-forming capacity of Chinese hamsters to NMU. ●, Untreated cells; △, cells from colonies "converted" by 10  $\mu\text{g}/\text{ml}$ . NMU; ○, cells from colonies "converted" by 100  $\mu\text{g}/\text{ml}$ . NMU.

One feature of great interest to have emerged from this work is the contrast between the *in vitro* behaviour of NMU and DMN. In addition to its properties as a direct acting carcinogen<sup>2</sup>, the former is known to be mutagenic in *Drosophila*<sup>15</sup>, *Saccharomyces*<sup>16</sup> and *Arabidopsis*<sup>17</sup>. DMN, by contrast, acts indirectly on the liver as a carcinogen<sup>2</sup>, and, while inducing mutations in *Drosophila*<sup>18</sup>, lacks mutagenicity for *Neurospora*<sup>18</sup> or bacteria<sup>19</sup>. These facts, and our observation that DMN fails to convert Chinese hamster cells in tissue culture, support the suggestion<sup>20</sup> that DMN only becomes an active carcinogen after having been acted on by an enzyme. While the mammalian liver and *Drosophila* contain this enzyme, *Neurospora*, *Escherichia coli*, and Chinese hamster fibroblasts presumably do not possess enough of it to convert DMN into an active form.

We thank Dr. P. N. Magee for the gift of chemical compounds, as well as much helpful discussion, and Mr. J. Green for technical assistance.

# Ecology of Aldabra Atoll

by

D. R. STODDART

Department of Geography, University of Cambridge

C. A. WRIGHT

Department of Zoology, British Museum (Natural History), London

The Royal Society made public on February 22 its concern that the island of Aldabra might be used as an air staging post and transmitting station. The island ecosystem of Aldabra is of great interest to biologists. The authors visited the island during 1966, and Dr. Stoddart will return with the Royal Society Expedition to Aldabra this summer.

SINCE the time of Darwin and Wallace it has been recognized that the biology of remote islands is of particular significance in evolutionary theory, and in the study of the dispersal, colonization, and speciation of plants and animals. Much work has been done on these problems both in low-latitude islands such as the Galapagos and Hawaiian groups, and more recently in the high volcanic islands of the Southern Ocean<sup>1</sup>. The small and relatively simple range of habitats and biota on islands suggests that insular ecosystems be used as models for more complex systems, forming natural laboratories for the study of ecological and evolutionary problems<sup>2</sup>.

As such problems have been formulated, however, the natural ecosystems of many islands, particularly in the Tropics, have been transformed, either by mining, by plantation agriculture, or more drastically in the past thirty years, by their use for airstrips, military bases and weapon-testing grounds. Recent proposals to locate a Ministry of Defence air staging post and B.B.C. transmitting station at Aldabra Atoll in the south-west Indian Ocean have caused considerable concern<sup>3</sup>, for Aldabra is one of the least disturbed of all low-latitude islands, and for historical and environmental reasons possesses an exceptionally rich and interesting fauna and flora<sup>4</sup>.

Aldabra is situated 260 miles north-west of Madagascar and 400 miles from the coast of Africa (Fig. 1). It is an elongate atoll, 21 miles long and up to 9 miles wide, with a land area of 60 square miles, and a total area, including the central lagoon, of 141 square miles (Fig. 2). Like a number of adjacent islands, it has been slightly elevated and the land rim now consists of eroded coral reef and reef-flat deposits, with maximum elevation of the solid rock of 15–20 ft. above sea-level, and some dunes rising to 50 ft. A general distinction may be made between two types of surface—champignon and platin<sup>5</sup>. Champignon consists of uplifted peripheral atoll reefs, intricately “dissected” by salt-water and brackish-water. The sharp, pinnacled surface is interrupted by numerous deep, steep-sided solution holes. Platin, on the other hand, is formed from raised detrital back-reef deposits modified by freshwater solution. The surface is flatter and lower than the champignon, and dimpled with solution pans. These contain freshwater pools which change size considerably with the transition from the wet (January–March) to the dry seasons: the annual rainfall is unknown, but may reach 50 in. The main platin area, of 14 square miles, is at the east end of the atoll, on South Island, where it is fringed towards the sea by champignon, partly overlain by dunes, and towards the lagoon by mangroves. The lagoon itself is shallow, and large areas dry out at low water; active coral growth is restricted to the margins of Main and East Channels. On the seaward side of the atoll there is a narrow wave-cut platform, which lacks flourishing coral reefs and which is backed by undercut champignon cliffs up to 15 ft. high. Beaches are small and few in number, though sand dunes have built up along the seaward edge of the champignon on the south side of the atoll.

The distinction between platin and champignon is of direct ecological importance because it corresponds to a distinction between two main types of vegetation<sup>6</sup>, which in turn are strongly correlated with faunal distributions. Champignon is covered with a dense thicket of *Pemphis acidula* which is almost impenetrable. There is virtually no soil except in the bottom of some potholes and the bare rock surface supports sparse tufts of *Mariscus ligularis* and *Eragrostis riparia*. Platin is covered with a more open mixed scrub of *Euphorbia abbotii*, *Thespesia populnea* and other trees, and an irregular turf of *Fimbristylis spathacea*. *Pandanus* forms conspicuous clumps around the larger freshwater pools. Hemsley<sup>7</sup> has compiled a flora of Aldabra, totalling some 173 species, of which 10 per cent are thought to be endemic.

Oceanic isolation combined with relative proximity to Africa and particularly Madagascar, together with the wide range of habitats presented by an uplifted compared with a sea-level atoll, have resulted in the development of an unusually rich fauna at Aldabra. The inhospitability of the environment, the scarcity of potable surface water, the lack of soil for growing coconuts, and above all the absence of workable guano deposits<sup>8</sup>, have meant that Aldabra has preserved its isolation while neighbouring islands such as Assumption have been drastically exploited by man.

Indigenous mammals are represented only by two insectivorous bats, and by an endemic fruit-bat, *Pteropus alda-branus*<sup>9</sup>. It is the giant land tortoise *Testudo gigantea*, however, which is of greatest interest and importance in the land fauna<sup>10</sup>. With those of the Galapagos Islands (*T. elephantopus*), the land tortoises of Aldabra form the only surviving natural populations of the giant form. In the early eighteenth century, *T. gigantea* was found on islands from Madagascar to the Seychelles, the Mascarenes, and even to the Chagos Archipelago (Fig. 1). Changes in habitat, competition from introduced animals and above all predation by man led to the disappearance of wild herds on all islands except Aldabra by 1840. Tortoises are now concentrated on the platin at the east end of South Island, where, during the dry season, they wallow in the drying freshwater pools during the early hours of the day and retreat to the shade of *Pandanus* when the sun is high. During the wet season, when large areas of platin are flooded by freshwater, they are probably more active and then breed. Despite a number of nineteenth century references to small or declining numbers, it is certain that the tortoise population now exceeds ten thousand. Tortoises feed on the *Fimbristylis* turf and the lower leaves of shrubs. Any attempt to move them to less favourable habitats on champignon would undoubtedly lead to considerable mortality. In addition to the tortoises, land reptiles are also represented by two geckos and a skink<sup>11</sup>.

The insects of Aldabra are fairly well known as a result of intensive collecting by Abbott<sup>12</sup>, Voeltzkow<sup>13</sup>, Fryer<sup>14</sup> and, more recently, by Legrand<sup>15</sup>. More than 350 species are recorded, with dominantly East African and Madagascan affinities; this compares with less than a hundred

species on most of the sea-level Indian Ocean atolls<sup>16</sup>. So little is known of the insect faunas of neighbouring islands that the degree of endemism is uncertain, but Legrand's recent monograph of the Lepidoptera<sup>15</sup> records thirty-five endemic species and twelve endemic sub-species in a total of 127 species. There is also a single earthworm, a common scorpion, several spiders and an inadequately known land mollusc fauna which includes one endemic species *Rhachistia aldabrae*<sup>17</sup>. The robber crab *Birgus latro* is common. A rich freshwater fauna has been found in the platin pools, including crustaceans (fairy shrimps *Streptocephalus* sp., conchostracans *Eulimnadia* sp. and ostracods *Heterocypris* sp.) and molluscs (notably a species of *Bulinus*). One freshwater "well" also contains a semi-freshwater fish of the gobiid genus *Tamanka* not previously recorded.

The birds of Aldabra<sup>18</sup> are interesting for two reasons: first, the presence of a number of endemic species and sub-species of land birds<sup>19</sup>, which are closely related to the land birds of Madagascar and the Comoros; and second, the existence of large breeding colonies of sea birds. Among the land birds the drongo *Dicrurus aldabranus* is most distinct.

Possible endemic sub-species include a fody *Foudia aldabrana*; a sunbird *Nectarinia souimanga*; a white-eye *Zosterops maderaspatana*; a turtledove *Streptopelia picturata*, and blue pigeon *Alectroenas gonzini*; a nightjar *Caprimulgus madagascariensis*; the coucal *Centropus toulou*; the kestrel *Falco newtoni*; the sacred ibis *Thres-*

*kiornis aethiopica*; and a rail *Dryolimnas cuvieri*. The flightless rail is now the last of the flightless birds of the Indian Ocean islands, which once included the dodo and the solitaire. On Aldabra it is now found on Middle Island since cats were introduced, the spread of which to Middle Island would clearly soon lead to the bird becoming extinct. Other larger birds, such as the sacred ibis and a flamingo *Phoenicopterus ruber*, are now only found at the east end of the atoll far removed from the small human settlement at West Island. Sixty years ago the flamingo probably numbered 500–1,000 individuals; now there are probably no more than fifty<sup>20</sup>.

Of the sea birds, frigates *Fregata minor* and *F. ariel* and pink-footed boobies *Sula sula* nest in great numbers on the mangroves of Middle Island. The frigates greatly outnumber the boobies and spend the day soaring to great heights over the eastern end of the atoll and diving to drink on the wing at freshwater pools on South Island. The Aldabra frigate colonies serve as the major breeding ground for the frigate population of the western Indian Ocean and a considerable non-breeding population certainly exists in this area (Bourne, W. R. P., personal communication). Other sea birds<sup>21</sup> include tropicbirds *Phaethon lepturus lepturus* and *P. rubricauda rubricauda*, terns *Sterna fuscata* and *S. sumatrana mathewsi*, fairy terns *Gygis alba monte* and noddies *Anous stolidus pileatus*. The most common shore birds include little egrets (*Egretta garzetta*), which show dimorphism as in Madagascar, and

Fig. 1. Location of Aldabra in the western Indian Ocean. The islands underlined are those where the giant land tortoise existed in the eighteenth century, according to Rothschild (ref. 10).

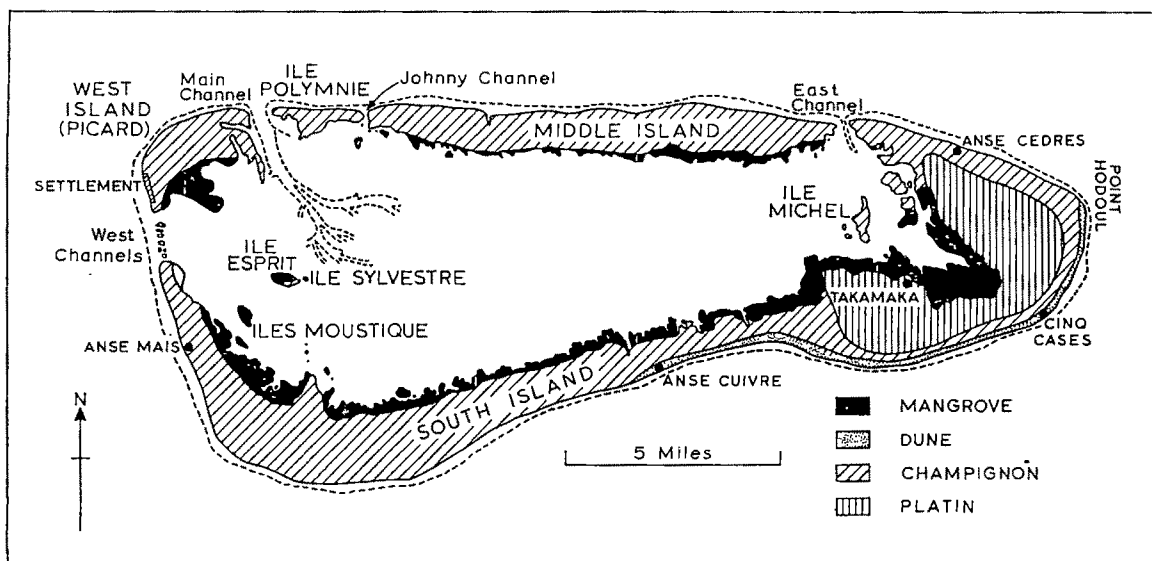

Fig. 2. Main terrestrial habitats of Aldabra Atoll.

the grey and little green herons *Ardea cinerea* and *Butorides striatus*. Large numbers of wading birds feed on drying sand flats in the lagoon at low tide.

Knowledge of the marine biota of Aldabra is particularly inadequate, though the brachyuran decapod crustacea have recently been reviewed by Guinot<sup>22</sup>. It is known that Aldabra, Cosmoledo and Assumption form the largest breeding ground for green turtle *Chelonia mydas* in the Indian Ocean<sup>23</sup>. Commercial exploitation has led to a catastrophic decline in breeding numbers despite protective legislation. The hawksbill *Eretmochelys imbricata* is also exploited and is declining in numbers. The green turtle population is thought to migrate from the Mozambique Channel, and breeds at Aldabra from February until September; however, no field study of this reptile has ever been carried out. The coral reef fauna appears to be poor and the prospects for commercial fisheries are also disappointing<sup>24</sup>. Studies are needed of marine algae, marine mollusca and other groups.

An attempt was made by Norwegians to colonize Aldabra in 1879, but the present settlement began with the first commercial lease of the atoll in 1888. A small group of Seychellois labourers, now numbering up to 100, takes turtle, fish and timber from the atoll. Within a few years of the first lease being granted, coconuts and other cultivated plants were introduced at the West Island settlement and other small beaches, together with weeds and domestic animals. As a result, there are now feral goats, dogs, cats, rats and mice at Aldabra. Large herds of feral goats have been described in the past, but few were seen in 1966; their role in modifying the island ecosystem remains unclear. Most of the introduced mammals are confined to South and West Islands, and have not yet reached the sea birds and the flightless rail of Middle Island.

Concern over the exploitation of Aldabra and the "imminent extermination of the Gigantic Land-Tortoises of the Mascarenes" was first expressed in a letter sent to the Governor of Mauritius in 1874 by a group of scientists which included Charles Darwin, Richard Owen, and Joseph Hooker. Even at that time it could be stated that "Aldabra is now the only locality where the last remains of this animal form are known to exist in a state of nature", and it was argued that:

"The rescue and protection of these animals is, however, recommended . . . less on account of their utility . . . than on account of the great scientific interest attached to them. With the exception of a similar tortoise in the Galapagos Islands (now also fast disappearing), that of the Masca-

renes is the only surviving link reminding us of those still more gigantic forms which once inhabited the continent of India in a past geological age. . . . It flourished with the Dodo and Solitaire; and whilst it is a matter of lasting regret that not even a few individuals of these curious birds should have had a chance of surviving the lawless and disturbed conditions of past centuries, it is confidently hoped that the present Government and people . . . will find a means of saving the last examples of a contemporary of the Dodo and Solitaire"<sup>25</sup>.

Protective legislation has been enacted from time to time by the Government of the Seychelles, mainly to protect the turtle industry and certain birds, and under the terms of the present commercial lease, granted in 1955, the whole of South Island, where it is planned to build an airfield, is designated as a nature reserve. Legislation in effect in 1965 under the laws of the Seychelles continues to apply under the new administrative arrangements whereby Aldabra forms part of the British Indian Ocean Territory<sup>26</sup>.

No major scientific studies have been carried out at Aldabra since J. C. F. Fryer's work in 1908-9. The relatively undisturbed character of the Aldabra ecosystem, the overriding importance of its population of the giant tortoise, its great sea bird breeding colonies and distinctive land birds, and its green turtle breeding grounds all require detailed study. Based on a reconnaissance expedition in 1966, conservation plans are being made in the event that the Ministry of Defence decides to proceed with the construction of an airfield, harbour and other facilities, and the B.B.C. with a transmitting station. At the same time, the Royal Society, after consultation with other scientific bodies, is organizing an expedition to make urgent scientific investigations before any disturbance takes place. This expedition, involving fourteen scientists, will last from August 1967 to March 1968, spanning both dry and wet seasons, and will cover both marine and terrestrial ecology. If development proceeds, the expedition will provide basic data for conservation planning, while if the present plans are abandoned, it will lay the groundwork for long-term scientific studies of an undisturbed island ecosystem unique in the Indian Ocean and perhaps in the world.

The 1966 scientific reconnaissance was made possible by the courtesy of the British Broadcasting Corporation and the Ministry of Defence, and by the support of the Royal Society. We thank the former Minister of Defence for the Royal Air Force, Lord Shackleton, and the Hydrographer, Rear-Admiral G. S. Ritchie, for their active interest; and Mr. A. Bosworth, British Broadcasting

Corporation, expedition leader; Mr. C. E. Loveridge, Ministry of Public Building and Works; Wing Commander P. A. S. Thompson, Ministry of Defence; Sir George Taylor, Director of the Royal Botanic Gardens, Kew; Dr. W. R. P. Bourne; and Dr. F. R. Fosberg, for their aid. The late Professor C. F. A. Pantin gave much initial encouragement.

## From Practice to Theory and Back

by

R. EDGEWORTH JOHNSTONE

Department of Chemical Engineering,  
University of Nottingham

Should engineers be taught at university in the same way as scientists? In what follows, the author expands on a talk to the Midlands Branch of the Institution of Chemical Engineers at Loughborough University on February 22.

ENGINEERING is an activity which begins with practical problems and ends with practical solutions. It calls for an understanding of science and the ability to apply it, but most engineers are not primarily scientists. The object of this article is to suggest that the university education of engineers is too closely modelled on that of scientists and that, as a result, most graduates leave university with an insufficient range of knowledge to enable them to practise successfully as engineers. Industry is obliged to teach them not only skills but also principles and techniques which could have been learnt earlier.

It is important to distinguish between skill, which must be developed on the job, and knowledge, which is more easily acquired away from it. (Skill in this sense is not necessarily manual, it may be technical or managerial.) Skill is the product of experience; knowledge can also come from experience but is best inculcated by systematic teaching. The practice of engineering calls for both knowledge and skill, and therefore graduates are not recognized as fully qualified engineers until they have had some years of responsible experience. In this respect the British system of education is ahead of most others. In the interests of economy, however, the knowledge and skill which an engineer needs should each be imparted to him by the most efficient means. For developing skill there is at present no satisfactory substitute for experience on the job. The inculcation of knowledge, however, is the specialized function of schools, colleges and universities, and one in which they have considerable expertise. One might therefore suppose that the universities and colleges ought to give the young engineer the knowledge he needs, and industry should provide the requisite experience, neither side encroaching on the function of the other.

This is not quite what is happening. Apart from, and in addition to, the required period of responsible experience, there is a trend in industry towards formal courses lasting for 1 or 2 years in which the graduate has the status of a trainee and is instructed in subjects such as organization and management, work study, economics and costing, factory legislation and so forth as well as in company practice. Courses of this kind proliferated after the Second World War when industrial companies found that by

setting up training schemes they could recruit engineering graduates direct from the universities and bypass national service. In chemical engineering, where the apprenticeship system had never been customary, there were no graduate training schemes known to the Institution of Chemical Engineers in 1946. By 1960, when national service ended, forty-seven approved schemes were in operation. In 1965 the number had risen to fifty. The continued existence of these courses, which must be quite costly to the firms concerned, suggests that they are meeting a genuine need. It must be a need peculiar to the United Kingdom because little if any formal training in industry is to be found elsewhere.

The continued need for graduate training schemes in Britain is in part a reflexion on the universities. In so far as the training imparts knowledge as well as skill it is doing a job which could have been done, and possibly done better, in a teaching establishment. The report of the Bosworth committee<sup>1</sup> recommends an industrial training course for electrical and mechanical graduates lasting for between 1 and 2 years; but it was strongly represented to the Bosworth committee, especially by young graduates, that several elements of the proposed training could with advantage replace less relevant material in the undergraduate course. My own experience in industry was that formal graduate training schemes tended to be unpopular both with the graduates themselves and with the middle and lower ranks of professional engineers who were expected to do the teaching. The former are tired of being *in statu pupillari* and eager to get their teeth into a responsible job; the latter already have a full-time job and may not like teaching anyway. Perhaps, therefore, the universities ought to look more closely at the work an engineer is required to do and consider whether they could not provide a more useful tool kit.

Engineering achievement is a product of four factors—knowledge, time, money and men. The term "product" is used in a quasi-arithmetical sense; if any one of these factors is zero then the total achievement is nil. If one factor were unduly low, then it would be necessary to increase some or all of the others in order to achieve a given result. Universities quite properly concern them-

selves with the factor of knowledge, but it tends to be limited to a knowledge of what is called engineering science. The principles which govern efficient management of time, money and men are supposed to be learnt by experience. This supposition may have been justified when industry was managed by rule-of-thumb, but today there are techniques and disciplines which largely replace rule-of-thumb and which can be systematically taught. For example, the more sophisticated applications of method study, critical path planning, linear and non-linear programming, cost-benefit analysis, project evaluation, and organization analysis. The logical content and level of abstraction of these disciplines of thought render them at least as "educational" as some of the subjects now studied. Furthermore, most engineers are unlikely ever to acquire a thorough grounding in the principles involved unless they get it at the university.

A competent engineer must be able to do three things: (1) translate a practical problem into a theoretical problem; (2) solve the theoretical problem; (3) convert the theoretical solution into a practical solution.

University engineering education concerns itself primarily with stage 2; yet it is a common experience among engineers that the greatest difficulties often arise in stages 1 and 3. There are areas of knowledge not usually touched on in engineering courses, such as those mentioned in the previous paragraph, which can help in both these stages.

In stage 1 the first task is to determine what the problem actually is. In any real situation the engineer is usually faced with a confused mass of information, some of which is conflicting and most of which is irrelevant. The correct selection of the relevant variables and parameters and the construction of a simplified conceptual model of the system may be more than halfway towards a solution of the problem. In this respect the numerical "examples" worked by university students are largely unreal because the relevant data have already been selected by the examiner. It may be possible for university teachers to adapt and to use some of the newer techniques of thought which have been developed in industry, such as formal critical examination<sup>2</sup> and PABLA (problem analysis by logical approach)<sup>3</sup> in order to inculcate the habit of asking the right question before rushing in to give the answer.

Stage 3 is the creative stage of the work of an engineer. Here the kind of detail which was discarded in stage 1 must be reintroduced in order to convert the theoretical solution into a workable piece of hardware or a practicable procedure. The type of thinking required is no longer the abstract analysis of pure science but a faculty that might be called "physical imagination". Analysis raises the thinker from the concrete to the abstract level of thought; imagination returns him from the abstract to the concrete, an equally difficult transition. The good engineering designer, having calculated his theoretical design parameters, must create in his mind's eye a detailed image of the final product and must conduct imaginary experiments with it in order to arrive at the best arrangement. Similarly a good managing engineer must visualize in advance the effects of alternative decisions. How to develop in students the faculty of physical imagination is a major problem. A start might be made by substituting freehand engineering drawing for the drudgery of the tee-square, as is already done in some American colleges, and requiring all solutions of problems to be supported by dimensioned sketches of equipment. Works visits and vacation employment in industry are helpful in stocking the student's mind with images of actual plant.

Physical imagination is the faculty which above all others distinguishes the born engineer from the born mathematician or pure scientist. It is the source of invention as opposed to discovery, and is so important that perhaps a special test should be given by engineering schools to pick out applicants who possess this faculty. It can be further developed during the course by the use of

graphical and geometrical concepts wherever possible as well as by open-ended problems which exercise the imagination. The technique of formal critical examination<sup>2</sup> which was mentioned under stage 1 can also be used to encourage creative imagination in design. As developed and used in the I.C.I. organization it involves the following basic sequence: (1) uncritical imagination throwing up a set of possibilities; (2) critical examination of these possibilities; (3) decision on the course to be followed. These are, of course, the stages of all creative thought, but in the method referred to they are systematized in such a manner that no possibility, however unusual, is likely to be overlooked. The first response of undergraduates to this technique is sometimes completely wooden; but in the more imaginative it soon releases a flood of ideas and enthusiasm. Furthermore, the habits of thought which it engenders are of permanent value in every kind of enterprise.

Little need be said here about management education proper, because British universities are at last awakening to the importance of this subject. For the most part, however, management studies appear to be developing in the context of economic and social science rather than of engineering. It is therefore worth emphasizing that to a practising engineer management principles are at least as important as mathematics. Engineering is a large-scale activity which requires the directed and co-ordinated efforts of many different groups and individuals. If the direction and co-ordination are inefficient, then, however good the scientific work, the total engineering job will be done badly. Many of the complaints about British engineering arise from management failures; for example, poor inspection or the late completion of projects. It is often argued that management principles should not be taught until experience has been gained in industry. The short answer to this is that only a small number ever attend post-experience courses. If some knowledge of management theory is to reach all engineers, then it must figure in the undergraduate syllabus.

Another common criticism of engineers is that they are bad at expressing themselves and communicating ideas. This is sometimes treated as a lack of skill in the use of English, and classes in grammar and composition are established to remedy it. The writings of students often reveal a more fundamental defect—the inability to think logically and present a reasoned case. It is a curious fact that in universities logic is not taught to those who have most need of it, especially scientists and engineers. All engineering students would profit from a course of instruction in symbolic and applied logic designed both to introduce them to the computer and to sharpen their ordinary thinking.

If, in order to produce a more balanced undergraduate course, university engineering departments were to interest themselves in the non-engineering science subjects mentioned here, some members of the academic staff would inevitably be drawn into research in these fields. This would be of benefit to industry as well as to the universities. The new planning and programming techniques have been developed to meet urgent practical needs, and their theoretical foundations have not always been very thoroughly explored.

Any attempt to broaden university engineering curricula is certain to meet with the objection that engineering courses are already overloaded and have no room for additional material. This argument betrays a complete misunderstanding of the problem. There is no received corpus of engineering knowledge that must be transmitted inviolate to the undergraduate. Engineering is a vast subject and only a very small part of it can be taught during the 3 or 4 years of an engineering course. The problem is to fill the short time available with whatever is most valuable. Dr. D. G. Christopherson<sup>4</sup> once observed that the overloading of this curricula stems not from demands by industry and the institutions but from the

way in which academics force their pet subjects into the syllabus.

It is easy to add material to a university curriculum but difficult to take it out on account of the internal pressures and interests alluded to above: thus, the chronic overloading. In my experience the only instrument that can overcome these pressures is factual information about the sciences and techniques which engineers are currently using; not the opinions of the professors, nor the opinions of employers (who sometimes do not know what their engineers are really doing), nor even the opinions of the engineering institutions, but objective first-hand data derived from a systematic survey. This has been done among chemical engineers and the two surveys conducted in 1960 and 1965 (refs. 5 and 6) provide quantitative data on the relative usage of different subjects. Professor S. P. Hutton has carried out a somewhat similar exercise among mechanical engineers<sup>7</sup>.

When all these arguments are admitted, however, it may be found that 3 years is too short a period in which to give young engineers the minimum equipment they will need if these additional aspects are to be covered. The present conjunction of overloaded syllabuses at universities with further instruction in industry might seem to support this view. In fact, much of what has been advocated would involve changes in emphasis rather than added matter; nevertheless, the possibility must be faced that 3 years may simply not be long enough. It is then a straight choice between teaching the additional material in industry or extending the university course. At present there is no factual evidence on the efficiency of teaching in industry as compared with that in the universities. What is needed is an independent survey of existing graduate training schemes and an assessment of the quality of the teaching and the amount of knowledge gained by the trainee. I feel that a teaching institution is likely to teach more efficiently than an industrial organization: consequently everything that is teachable at the university should be taught there.

If university engineering courses are to move closer to engineering as it is actually practised, certain changes will be necessary in the make-up of the academic staff. It ought to contain a leavening of engineers with industrial experience at all levels of seniority. This is because it is not possible to practise engineering at a university in the sense that one can practise science. As the industrial experience of a university teacher recedes into the past he inevitably becomes less of an engineer and more of a scientist. Consulting work may delay but cannot arrest this gradual loss of touch. How to attract mature engineers of high calibre into university teaching is a problem which should not be insoluble. One way not to attract them is to insist that applicants for senior academic posts in engineering shall always be able to produce long lists of publications. It may be more relevant to enquire what plants they have designed, built and operated, and what projects they have carried through successfully.

This, then, is a plea for universities to pay greater attention to stages 1 and 3 of the engineer's task and provide a more adequate conceptual framework for the creative imagination of the designer, the diagnostic skill of the trouble-shooter, and the organizing ability of the managing engineer. The aim should be to produce a graduate who will be fit for responsible employment in a period of months rather than years.

## BOOK REVIEWS

### ALL ABOUT ALCOHOL

#### Alcoholism

*Mechanism and Management.* By Max Hayman. (A Monograph in the Bannerstone Division of American Lectures in Living Chemistry.) Pp. xv + 315. (Springfield, Ill.: Charles C. Thomas, 1966.) \$10.50.

MODERN films tend to open with an arresting scene—a burglary or murder—with which the subsequent action deals in more conventional fashion. In much the same way this book begins with a staggering list of facts about alcoholism, which become the more impressive for their presentation in this way.

The state of California (population about 17,500,000) had 886,000 alcoholics in 1962: it runs a close second to New York with 8,170 alcoholics in every hundred thousand of population more than twenty years old. In hospital in the United States as a whole alcoholism ranks fourth in the list of public health problems. These are just a few of the facts recorded.

The book is addressed to medical men, whether general practitioners or specialists. In so far as several chapters deal with psychoanalytic theory and practice in relation to alcoholism, it is meant for American doctors, whose medical training and orientation are such that they would feel the need for some presentation in these terms. The author, who has unrivalled experience in all aspects of alcoholism, makes it clear, however, that very few alcoholics are suitable for, or receive, formal psychotherapy of this kind, and that eclectic methods involving a wide range of skills and professions suit the majority of the sufferers best.

Alcoholism is presented as a medico-social problem, affecting human life at very many points. Certain selected aspects, biochemical, psychological, legal, psychiatric, pharmacological and others, are chosen for succinct review in relatively short chapters, each of which is followed by an excellent list of the most relevant publications. This design precludes an evaluation in great depth in any area, but has the advantage of covering the whole field in readable fashion, while giving the more sophisticated reader plenty of leads for pursuing a particular interest.

D. L. DAVIES

### PULMONARY CIRCULATION

#### Pulmonary and Bronchial Vascular Systems

*Their Reactions under Controlled Conditions of Ventilation and Circulation.* By I. de Burgh Daly and Catherine Hebb. (Monographs of the Physiological Society, Vol. 16.) Pp. xv + 432. (London: Edward Arnold (Publishers), Ltd., 1966.) 90s. net.

DR. I. DE B. DALY's published contributions to the study of pulmonary circulation extend over forty years, and he and Dr. Hebb between them have used each one of the experimental approaches discussed in this book.

The book opens with an account of the functional anatomy of the lung, which lays the essential foundation for the evaluation of subsequent experimental results. Important quantitative data on lung architecture are assembled and species differences are illustrated by

hitherto unpublished photomicrographs by Dr. Hebb. Two important conclusions emerge from an examination of the literature on the interrelation between bronchial and pulmonary circulations: that changes in pulmonary vascular flow and resistance may be secondary to changes in the bronchial circulation, but, on the other hand, the functional interrelationships between the two circulations demonstrated in experimental conditions can be very different from those in the intact animal. All the work on the pattern of innervation of the lung was done until very recently with the use of silver or methylene blue staining—both methods with severe limitations. The results obtained with recent histochemical methods—Koelle's method for cholinesterases and Hillarp and Falck's for catecholamines and 5-hydroxytryptamine—are reviewed and recent results obtained by Dr. Hebb are included. The use of Hillarp and Falck's fluorescence method is likely to solve many unanswered questions. The discussion in the chapter on haemodynamics is relevant to problems beyond those of the pulmonary circulation and includes very valuable comments by L. E. Bayliss on Burton's theory of critical closing pressure. The chapter concludes with an examination of the complicating effects on pulmonary blood flow introduced by lung inflation and stroma stresses. The next chapter is concerned with the criteria for distinguishing primary pulmonary vasomotor responses from secondary or passive effects on the pulmonary circulation caused by changes in the bronchial circulation, in airway diameter or lung volume. This allows a critical evaluation to be made of the experimental results described in the remaining five chapters.

Chapters six and seven deal with the voluminous, conflicting and confusing literature on pharmacological experiments, using the acetylcholine family of drugs (including analogues, blockers, potentiators), the catecholamines and 5-hydroxytryptamine. To the authors' many reservations in the interpretation of the results with drug applications another could be added: recent evidence from fluorescence and electron microscopy has shown that the nerve fibres in most blood vessels are restricted to the medio-adventitial junction. The chemical transmitter released by the nerves, therefore, gains access primarily to the outer layer of the media. This cannot be mimicked by either intravascular injection of the drug or soaking a ring of blood vessel in solutions containing the drug.

The final three chapters deal with the effects of various ventilating gas mixtures, and of nerve stimulation on the pulmonary circulation and the problem of pulmonary vasomotor reflexes. Earlier workers failed to get results with nerve stimulation. Dr. Daly showed that survival of the nerve supply depended on the bronchial circulation. His pioneering work on lung perfusion technique is contained in an invaluable appendix. Using perfused lung preparations Dr. Daly in collaboration with M. de B. Daly has provided important evidence for pulmonary vascular reflexes from the carotid body and carotid sinus.

The great value of this book lies in the rigorous examination of a number of basic problems and the stepwise synthesis of a picture of an integrated physiological system.

MARIANNE FILLENZ

## PARASITE COLLOQUIUM

### Host-Parasite Relationships

By James E. McCauley. (Proceedings of the Twenty-sixth Annual Biology Colloquium, April 23-24, 1965.) Pp. 148. (Corvallis: Oregon State University Press, 1966.) \$4.50.

THE twenty-sixth annual Biology Colloquium, held in April 1965 at Oregon State University, was attended by six specialists in the subject of host-parasite relationships, whose contributions are published in full in this booklet

of 148 pages, edited by J. E. McCauley. J. F. Mueller, who has for years made a study of diphyllbothriid tapeworms, describes many aspects of *Spirometra mansonioides*, a parasite of carnivores most commonly found in domestic cats which harbour the adult worms and whose larval development takes place in copepods and reptiles. This paper is concerned mainly with the biology of larval stages in experimental animals and in *in vitro* culture; growth rate, immunity, weight gain and longevity of infected animals, and aberrant forms of the parasite are discussed in this beautifully illustrated article. H. W. Manter discusses the trematode parasites of fishes and their relationships with their hosts in regard to the information they convey both about their own geographical distribution and that of their hosts in ancient times; they also function as "indicators" of evolution in the same way as fossils provide information to palaeontologists. G. H. Ball investigated the relationship of the avian malaria parasite, *Plasmodium relictum*, to its mosquito host, by *in vitro* culture of the mosquito phase of the parasite, to determine its biochemical needs. His experiments have shown that the mosquito environment is not essential physiologically or biochemically for the development of the parasite, whose relationship to the mosquito's organs is an ecological one. J. R. Douglas and N. F. Baker are concerned with certain nematode parasites of the dog ("man's best friend"), particularly with *Toxocara canis*, which in the past decade has been shown to be a most unfriendly parasite, transmissible to human beings, sometimes with serious consequences. P. H. Silverman gives some immunological aspects of infection with helminth parasites and, by means of examples from the cestodes, nematodes and trematodes, he contrasts the mechanism of metazoan and microbial immunity. E. L. Schiller reviews the host-parasite relationship of members of the cestode genus *Echinococcus* from the ecological standpoint, with special reference to their occurrence in arctic wildlife and in man.

J. J. C. BUCKLEY

## ENVIRONMENT AND BEHAVIOUR

### Environmental Biology

Compiled and edited by Philip L. Altman and Dorothy S. Dittmer. (Biological Handbooks.) Pp. xxi + 694. (Bethesda, Maryland: Federation of American Societies for Experimental Biology, 1966.) \$15.

THIS handbook, prepared by the Federation of American Societies for Experimental Biology, attempts to bring together in a single publication the pertinent information relating to the effects of the environment on the behaviour of living organisms—plants and animals including man. The contents have been selected by an advisory committee comprised of R. L. Zwemer, A. R. Behnke, L. D. Carlson, H. J. Curtis, D. B. Dill, D. E. Goldman, R. A. McFarland, A. G. Norman, M. B. Russell and H. M. Webb, and prepared by some 450 biologists.

The information is classified in the first place in relation to one of ten major environmental factors. Under each heading the effects of various attributes of the particular environment on a particular biological function are stated where quantitative data are available. Most of the information is presented in tabular form with an introductory heading giving essential details about, for example, units of measurement, definition of terms, and followed by a citation of the literature from which the table has been prepared. Values are generally presented as the mean with either the standard deviation or the upper and lower limits of the range of individual values about the mean.

The first 120 pages of the handbook are devoted to temperature control and the effects of raised and lowered environmental temperatures on such varied biological quantities as body temperature, heart rate, cardiac output,

performance, growth of various mammals and rates of growth of bacteria, fungi and viruses. A section dealing with the effects of light and ionizing radiation occupies the next fifty pages and this is followed by a forty page section, the contents of which are devoted to the effects of sound, vibration and impact. The effects of acceleration and gravity are described in a twenty page section primarily in relation to man. The effects of the gaseous atmosphere on plants and animals are considered in three distinct sections totalling 180 pages, dealing with high and low concentrations of oxygen and carbon dioxide; total environmental pressure and atmospheric pollutants. The effects of water and solutes are considered in separate sections (with a total of 100 pages) primarily in relation to plants and aquatic animals. The tenth section of forty pages is devoted to biological rhythms. The book has two appendixes which give corresponding scientific and common names for animals and plants.

This handbook provides within a single cover a very extensive range of quantitative biological data. It is inevitable in a book of this type that some of the limitations of the value of particular groups of data are not apparent. In general, however, references to the literature are extensive and the book provides an easy method of access to the literature of fields outside a reader's normal sphere of knowledge. Thus, while the handbook could with advantage be held in the libraries of biological research and teaching institutions, the individual worker will probably find it of limited value in his own field.

J. ERNSTING

## LABORATORY BIOLOGY

### An Experimental Approach to Biology

By Robert G. Thomson and Peter Abramoff. Pp. xi + 253. (San Francisco and London: W. H. Freeman and Company, 1966.) 26s.

THIS laboratory guide contains protocols for thirty-five experiments in nine areas of biology, and it is clear that the authors are well aware of students' difficulties. An introductory section covers safety measures, cleaning glassware, preparing standard solutions, and the use of centrifuges and volumetric glassware, while appendixes deal with pH meters and colorimeters.

The book would prove useful to those planning sixth form and introductory university courses, although some caveats must be entered. The experiments on active transport through bags of frog's skin, and on the induction of ovulation by injecting frogs with pituitary extracts prepared from anaesthetized frogs, will require care if the spirit of the laws protecting animals is to be observed. Measuring the volume of gas produced by *Elodea* without further analysis gives misleading data on the production of oxygen—and to show that the gas turns pyrogallate brown merely demonstrates the presence of oxygen, not its concentration. A large water reservoir in potometers is an anachronism, and in any event transpiration is easy to estimate directly by weighing. Benedict's solution contains sodium carbonate, not bicarbonate.

These are errors which can be corrected in a second edition. The general standard of the book is high, and it can be recommended.

A. K. THOMAS

## STATISTICAL PAPERS

### The Selected Papers of E. S. Pearson

(Issued by the Biometrika Trustees to celebrate his 30 years as Editor.) Pp. vi + 327. (London: Cambridge University Press, 1966.) 40s. net.

THE journal *Biometrika* was founded by Karl Pearson, W. F. R. Weldon and Francis Galton in order that papers

on the applications of statistical method to biology and allied subjects might be published speedily and without hindrance from the editors of journals not specifically designed to cover such topics. The journal grew in circulation over the years but, such was the authority of Pearson in the statistical world, it remained very largely a house-journal until his death. When his son, E. S. Pearson, took over as editor in 1936 the statistical climate as well as the journal were changing. The proliferation of statistical centres all over the world was then beginning, which resulted in an outpouring of research papers which has grown steadily in volume until the present day.

*Biometrika*, the statistical world generally, and the English statistical world in particular owe much to E. S. Pearson's devoted and conscientious editorship during this climactic period. As ruler over a journal, still at the present day pre-eminent in England, he was able to influence to some extent the thinking of his contributors, and if we have not yet abandoned the search for common sense in data in favour of the hunting of the mathematical snark this is in part due to his careful refereeing and editing.

Much of E. S. Pearson's own work was published in *Biometrika* and it is fitting that the trustees should issue some of these papers to mark his retirement from the editorship. Out of the twenty-one papers all but three were first printed in the journal, half of them since 1945. A further volume, which will reflect his research activity in company with J. Neyman during the thirties, is promised in a short time. The papers republished in this present volume show Pearson's main interests over the years—non-normality, bases for the tests of hypotheses, analyses of accident data, approximations to probability distributions using moments.

It was a happy thought of the trustees to accompany this present volume with a volume containing the joint Neyman-Pearson papers and, in consort with the University of California Press, a volume of Neyman's own papers. Statisticians the world over will be grateful for their enterprise.

F. N. DAVID

## UNDERWATER SOUND

### Ocean Acoustics

Theory and Experiment in Underwater Sound. By Ivan Tolstoy and C. S. Clay. (Advanced Physics Monograph Series.) Pp. x + 203. (New York: McGraw-Hill Book Company, Inc.; Maidenhead: McGraw-Hill Publishing Company, Ltd., 1966.) 124s. 6d.

THE rather few monographs in this field tend to lean strongly toward either applied mathematics or engineering. This short volume holds admirably to a middle course, balancing mathematical analysis against experimental knowledge, and the idealizations required for a coherent theory against the real inhomogeneities and fluctuations.

The theme is acoustic propagation in shallow and deep water; sources, receivers and (except in one chapter) signal processing are purposely given little attention. The main attack is by normal-mode theory, in terms of eigenfunctions and eigenvalues rather than of residues in the complex plane. Ray methods and the intermediate WKB approximation are, however, carefully related to normal modes, and are used frequently. Geophysical and oceanographic complexities of the medium are constantly emphasized as limitations on feasible theory and on comparisons with experiment. Many such comparisons are given, numerically or graphically, with both clarifying and cautionary effects. Citations from the literature, averaging thirty in a chapter, amplify mathematical details, extend the theory, and give experimental results.

The preface succinctly outlines aims and methods, and the first chapter is an excellent compact account of the chief acoustical properties of the ocean. Thereafter, mathematical description builds up step by step. Successive chapters treat basic theory; normal modes; shallow-water propagation; deep-water propagation; effects of irregularities; and measurements as problems in filter theory. A brief chapter of conclusions goes beyond a résumé by outlining the need for carefully planned combinations of theory, measurement and statistical analysis if much more progress is to be made.

The book can be highly recommended to neophytes, but also to experienced workers heretofore daunted by differing, widely scattered and often over-formal presentations. No one could make this subject easy, but the authors hold to essentials, develop them systematically, and discuss them in a physical context.

A. O. WILLIAMS, JUN.

## DYNAMIC STARS

### Dynamics of Stellar Systems

By K. F. Ogorodnikov. Translated from the Russian by J. B. Sykes. Translation edited by Arthur Beer. Pp. xii+359+28 plates. (Oxford, London and New York: Pergamon Press, Ltd., 1965.) 100s. net.

TEN years after it was written this book can hardly read as a fully balanced account of the subject. In those years stellar dynamics has been re-enlivened by contacts with plasma physics, stellar element abundance work, celestial mechanics and ergodic theory, so it is no surprise to find little mention of those. The book's main emphasis, however, that stellar systems have settled to some form of detailed statistical quasi-equilibrium, is still well placed. No detailed theory of the relaxation process exists although it still seems likely that it is the large scale density fluctuations or star clouds that cause "irregular" gravitational fields and thus cause relaxation of stellar orbits. Even from the swarming workers on plasma physics no full theory of the relaxation of a collisionless medium has emerged. Recently computer experimenters and theorists have tackled this problem which lies at the basis of galactic dynamics. So far Ogorodnikov's assumption that the rotating self-gravitating Maxwellian distribution will be the outcome seems not too far from the truth; however, it appears that equipartition of kinetic energy will be replaced by an equality of the velocity dispersions of stars of different masses.

The book has other strong points. First, the emphasis that Schwarzschild's ellipsoidal hypothesis, though locally a good rough approximation, is actually false, so that theory based on its exact truth everywhere leads to nonsense. Second, there is the importance given to work on the third integral, a subject that has developed considerably since the book was written and which has even given rise to developments in celestial mechanics.

There are also weak points, however. The author has chosen to ignore work on evolution resulting from individual stellar encounters based on Chandrasekhar's dynamical friction. The Fokker-Planck equation and the difficult task of deriving the Fokker-Planck diffusion coefficients are hardly mentioned and the student is thus given few clues as to how to set up the mathematics necessary for a full discussion of the evolution of star clusters.

It is argued that apparent smoothness of the form of a galaxy must imply the presence of a dissipative viscosity. In fact such forms could be attained quite otherwise as a result of mere orbital propagation of the distribution function. These are perhaps matters of author's licence; the following error is not. In equations 4.44 and 4.45 approximate expressions for changes in velocity resulting from an encounter are compared and contrasted. Unfor-

tunately in one  $\Delta V$  is the change of relative velocity while in the other  $\Delta V$  is the change of velocity of only one of the two interacting bodies. Had this been taken into account disagreement would have been avoided.

Physicists and astronomers who have not looked at graded exposures of galaxies should be warned against "theorem III" on page 306. "In any dynamically determinate galaxy the star density if sufficiently smooth is constant in a first approximation and . . ." In practice one of the outstanding characteristics of most galaxies is the density contrast as one proceeds outwards from the centre. This is so great that all the central regions are normally burnt out on exposures that show the outer parts. The words "sufficiently smooth" are thus included in theorem III to eliminate all galaxies save a very few.

In spite of these shortcomings Ogorodnikov's book is clearly written and translated and is likely to be a standard text for some courses on stellar dynamics. It is a pity that students must be warned against certain passages, and above all it is a pity that the book was not brought up to date before it was translated.

D. LYNDEN-BELL

## GAS DYNAMICS

### Elements of Magnetogasdynamics

By L. E. Kalikhman. Translated by Scripta Technica, Inc. Edited by A. G. W. Cameron. (Saunders Physics Books.) Pp. xvii+366. (Philadelphia and London: W. B. Saunders Company, 1967.) 61s.

MAGNETOHYDRODYNAMICS is the study of the effects of electromagnetic body forces on a moving electrically conducting fluid. When the fluid is an ionized gas, when the processes are relatively slow, and when the energy of the magnetic field dominates that of the electric field a regime of the more general subject is defined by the title of this book. As such, it is of particular interest to astronautical engineers and those working in m.h.d. power generation.

The book is an American translation of a well known Russian text-book first published in 1964 and almost all of its references are to work from these two countries. It is basically a theoretical treatment, but is presented in a manner which the experimenter will find most useful. Russian authors have a good reputation for this engineering science approach and the translation has maintained the original spirit of the work.

This volume is to be recommended to the graduate engineer for the lucid manner in which the physical principles are introduced in the first two chapters; the physicist, generally unversed in fluid dynamics, will appreciate its treatment here. Aspects of steady state plasma flow without dissipation are followed by a discussion on shock waves in plasma. The sections on electrode-adjacent layers and the aerodynamic boundary layer in a plasma are the best collected accounts which I have seen. It is in the region between a solid surface and the body of a plasma that the majority of practical problems are to be found; for example, this region presents some of the critical problems in m.h.d. power generation.

More advanced chapters deal with two dimensional plasma flows in channels, unsteady state flows and hydrodynamic instabilities. A final chapter reviews, quite briefly, the practical applications of plasma propulsion, power generation and flight control, but references to experimental work appear throughout the book.

This book is a valuable contribution; unfortunately the subject has a more limited research effort in this country than it deserves.

# Cytochrome c and Evolution

by

T. YAMANAKA

Department of Chemistry, Revelle College,  
University of California,  
San Diego, California, and  
Department of Biology,  
Faculty of Science, Osaka University,  
Toyonaka, Osaka, Japan

A scheme for the evolutionary relationships of living organisms is proposed. It is based on data concerning the reactivities of cytochromes *c* of various organisms with cytochrome oxidase from a bacterium and from the cow; on the assumption that denitrifying organisms are the most primitive and on the similarity of haem *d* to chlorophyll.

ONE approach to the elucidation of the evolution of life on the Earth depends on taxonomic classification which derives from comparative biochemical investigations, especially of enzymes or functional proteins. Investigations of this type have been made by various workers<sup>1</sup>. It is necessary that components involved in such systems should occur widely throughout animals, plants and micro-organisms. Cytochromes are present in all aerobic organisms and in many anaerobic micro-organisms; they function as fundamental components in energy conversion biomechanisms. Among the cytochromes, cytochrome *c* is generally easily extractable by salt solution and the procedures for its purification have been established<sup>2</sup>.

As is well known<sup>3</sup>, there is a distinct biological specificity in the reaction of cytochrome *c* with cytochrome oxidases. This specificity can be used to detect very small differences between cytochromes *c*. It is of interest, therefore, to explore the possibility that interaction between cytochromes *c* and oxidases could provide a comprehensive basis for evolutionary investigations.

Two kinds of highly purified cytochrome oxidases are available: one is *Pseudomonas* cytochrome oxidase, which is isolated from *Pseudomonas aeruginosa* and obtained in a crystalline form<sup>3,4</sup>, and the other is cow cytochrome oxidase (= cytochrome *a*), highly purified from beef heart muscle<sup>5</sup>. *Pseudomonas* cytochrome oxidase reacts very rapidly with *Pseudomonas* cytochrome *c* but reacts very poorly with cow cytochrome *c*, whereas cow cytochrome oxidase reacts very rapidly with cow cytochrome *c* but does not react with *Pseudomonas* cytochrome *c*. Furthermore, cytochromes *c* of various organisms react with the two kinds of cytochrome oxidases at various rates<sup>3,4,6,7</sup>.

In the non-photosynthetic bacteria, cytochromes *c* of the denitrifying bacteria (*Pseudomonas aeruginosa*, *P. stutzeri* and *Micrococcus* species) react with *Pseudomonas* cytochrome oxidase very rapidly, but do not react with cow cytochrome oxidase. In this respect, the denitrifying bacterial cytochromes *c* are very similar to each other. The three kinds of *Micrococcus* cytochromes *c* shown in Table 1 are isolated from the same organisms. Their reactivities with cytochrome oxidases are qualitatively similar to one another, although quantitatively they differ considerably.

*Bacillus subtilis* cytochrome *c* reacts with *Pseudomonas* cytochrome oxidase poorly compared with the denitrifying bacterial cytochromes *c*, and it reacts with cow cytochrome oxidase very slowly. Thus, *Bacillus* cytochrome *c* is very different from the denitrifying bacterial cytochromes *c*.

In photosynthetic bacteria, cytochromes *c* react poorly with both cytochrome oxidases, except for *Chlorobium thiosulphatophilum* cytochrome *c* which reacts very rapidly with *Pseudomonas* cytochrome oxidase. *Chlorobium* is

§ Previously described as *P. saccharophila*.

¶ Cytochrome *c* is isolated from dark grown cells. All other cytochromes *c* of photosynthetic organisms are isolated from light grown cells.

|| Formerly reported as *S. cerevisiae*.

¶ Cytochrome *c* participates in respiration.

classified among the green sulphur bacteria, whereas *Rhodospseudomonas* and *Rhodospirillum* belong to the group of non-sulphur purple bacteria<sup>36</sup>. *Chlorobium* is very different from *Rhodospirillum* and *Rhodospseudomonas*, also on the basis of the enzyme properties of the associated cytochromes *c*.

There are two kinds of algal cytochromes *c*, derived from *Porphyra tenera* and *Navicula pelliculosa*, and these react with *Pseudomonas* cytochrome oxidase at appreciable rates, but do not react with cow cytochrome oxidase. On the other hand, *Euglena gracilis* cytochrome *c* reacts less with *Pseudomonas* cytochrome oxidase than do *Porphyra* and *Navicula* cytochromes *c*, and it does not react with cow cytochrome oxidase.

Among the fungi, yeast cytochromes *c* are very different from other microbial cytochromes *c* in that they react very rapidly with cow cytochrome oxidase. In this respect, they resemble animal cytochromes *c*, but they definitely differ from mammalian, bird and amphibian cytochromes *c* in that they react fairly rapidly with *Pseudomonas* cytochrome oxidase. On the other hand, although *Aspergillus oryzae* is classified with yeast in the Ascomycetes, its cytochrome *c* is very different from yeast cytochromes *c* with respect to reactivity with cow cytochrome oxidase. *Physarum polycephalum* cytochrome *c* reacts very poorly with *Pseudomonas* cytochrome oxidase, but reacts with cow cytochrome oxidase fairly rapidly.

In higher plants, wheat cytochrome *c*, isolated from the wheat germs, participates in respiration but not in photosynthesis. This haem protein shows reactivity with cytochrome oxidases similar to that of animal cytochromes *c*.

All animal cytochromes *c* are very similar, that is, they possess an  $\alpha$ -peak at 550 m $\mu$ , are basic proteins, react poorly with *Pseudomonas* cytochrome oxidase, and react very rapidly with cow cytochrome oxidase, although they are different from one another in their primary structures<sup>36</sup>. Bony fish cytochromes *c* are, however, distinguishable from other animal cytochromes *c*, because they react with *Pseudomonas* cytochrome oxidase fairly rapidly.

In Fig. 1, the various cytochromes *c* are arranged on the basis of their reactivities with both cytochrome oxidases. Along the abscissa the reactivity with *Pseudomonas* cytochrome oxidase is plotted. This can be assumed to correlate in some fashion with evolutionary time. The ordinate gives reactivity with cow cytochrome oxidase, and this may be assumed to be proportional to the extent of adaptation to oxygen of the organisms from which the cytochromes *c* are isolated. It is evident that cytochromes *c* of primitive organisms are situated in the lower left corner and those of higher organisms generally tend toward the upper right corner. Intermediate cytochromes *c* lie between the two corners. There are some cytochromes *c* in the lower right corner, but it is noteworthy that no cytochrome *c* has been found which is situated in the upper left corner.

Furthermore, we can note an important fact from Fig. 1; all cytochromes *c* that react very rapidly with cow cytochrome oxidase are situated to the right of algal cytochromes *c*. What does this mean? According to the present ideas, the primitive Earth atmosphere contained no molecular oxygen, which appeared on the Earth for the first time as a result of algal photosynthesis<sup>37</sup>. Results of our investigations agree with these ideas, that is, that after algal photosynthesis began, organisms appeared which utilized molecular oxygen.

From Fig. 1, it is suggested that the primitive cytochrome *c*, which reacts very rapidly with *Pseudomonas* cytochrome oxidase but not with cow cytochrome oxidase, could have evolved to the cytochromes *c* which react very poorly with *Pseudomonas* cytochrome oxidase, but react rapidly with cow cytochrome oxidase, and that various cytochromes *c* remain as intermediates in this evolutionary path. What could be a rationale for such evolution of cytochrome *c*? Before I discuss this question, however, I should like to speculate about the evolution of the respiratory system.

As already mentioned, it is believed that there was no molecular oxygen on the primitive Earth<sup>37</sup>. The most primitive organism seems to have appeared on the Earth

Fig. 1. Evolutionary relationships of organisms on the basis of reactivities of their cytochromes *c* with *Pseudomonas* and cow cytochrome oxidases.

in highly reducing conditions<sup>38,39</sup>. It could have obtained energy for its life processes by eliminating hydrogen from organic substances. The hydrogen was evolved into the atmosphere by means of a hydrogenase system<sup>40</sup>, that is, by oxidation of organic substances. Thereafter, some organisms may have appeared which could reduce molecular nitrogen by hydrogen (nitrogen fixation) instead of allowing hydrogen to be lost into the atmosphere<sup>40</sup>. Meanwhile, some organisms may have appeared which utilized sulphate as the terminal electron acceptor (sulphate respiration)<sup>41,42</sup>, and they could have had a primitive cytochrome system.

In sulphate respiration, however, the energy efficiency is low. When organisms use nitrate in place of sulphate, they can obtain energy more efficiently. Thus, the organisms which obtain energy by nitrate reduction (nitrate respiration)<sup>42,43</sup> could have appeared next, and it has been found that oxidative phosphorylation coupled with nitrate reduction occurs in the cell-free extracts of a few of the denitrifying bacteria in anaerobic conditions<sup>44</sup>. These organisms, however, must have encountered serious trouble in that nitrite, formed as the product of nitrate reduction, is poisonous. Thus, the organisms were required to elaborate a mechanism for elimination of nitrite, so that a nitrite reducing system appeared probably simultaneously with nitrate respiration.

It has been demonstrated that *Pseudomonas* cytochrome oxidase is the same entity as *Pseudomonas* nitrite reductase<sup>4,45</sup>. It is known that the nitrite reducing system of *P. aeruginosa* is composed of a highly developed cytochrome system<sup>4,46</sup>. Because the nitrite reductase functions also as a normal cytochrome oxidase, this cytochrome system is thought to have been able to participate

also in aerobic respiration after molecular oxygen appeared on the Earth.

The cytochrome systems which are observed in various aerobic organisms at the present time may have developed from a cytochrome system such as that present in *P. aeruginosa*. *Pseudomonas* cytochrome oxidase had a haem *d* (formerly called haem *a*<sub>2</sub>)<sup>46</sup> as its prosthetic group<sup>47</sup>. As shown in Fig. 2, haem *d* has two extra hydrogen atoms on one of the pyrrole rings, and in this respect it is similar to chlorophylls. The two extra hydrogen atoms of haem *d* are essential for the function of *Pseudomonas* cytochrome oxidase<sup>51</sup>. Probably because of the presence of two extra hydrogen atoms in haem *d*, *Pseudomonas* cytochrome oxidase is extremely labile in the presence of hydrogen peroxide<sup>52</sup>, and therefore the appearance of molecular oxygen on the Earth may not have been favourable to this cytochrome oxidase (haem *d*-bearing cytochrome oxidase); in aerobic conditions hydrogen peroxide is produced from oxygen by various enzyme systems (for example, by flavo-enzymes). The prosthetic group of the cytochrome oxidase, therefore, may have evolved from haem *d* to haem *a*. The latter is the prosthetic group of cow cytochrome oxidase (and of cytochrome oxidases of various aerobic organisms). The protein moiety of *Pseudomonas* cytochrome oxidase, however, does not function as a cytochrome oxidase with haem *a* as the prosthetic group<sup>51</sup>. The protein moiety which functions with haem *a*, therefore, may have appeared, resulting in the final evolution of haem *a*-bearing cytochrome oxidase. During the evolution of cytochrome oxidase, the protein moiety of *Pseudomonas* cytochrome *c* could have changed, leading to the possibility of reaction with various cytochrome oxidases, which appeared during

Fig. 2. Haems and chlorophylls<sup>44,46-50</sup>.

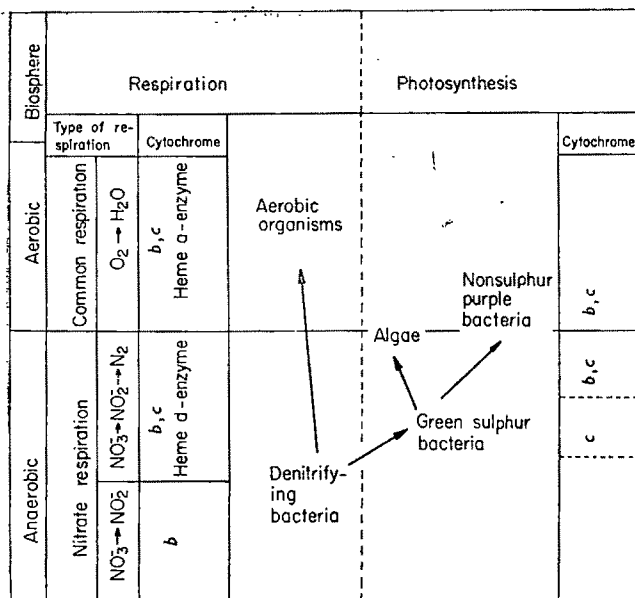

Fig. 3. Diagrammatic presentation of evolution from anaerobic organisms to aerobic organisms. (It has been claimed that a haem *a*-bearing cytochrome oxidase is present in dark grown cells of *R. sphaeroides*<sup>43</sup>.)

the evolution of cytochrome oxidase and which are still present in various organisms. Thus, on this basis, haem *d*-bearing cytochrome oxidase is more primitive than haem *a*-bearing enzymes.

As mentioned in the preceding sections, *Chlorobium* cytochrome *c* is similar to the denitrifying bacterial cytochromes *c* in its reactivities with cytochrome oxidases. On the present hypothesis, non-sulphur purple bacteria are more highly evolved (or more recent) organisms than green sulphur bacteria and algae. Furthermore, as mentioned previously, the structure of haem *d* is very similar to that of chlorophylls (Fig. 2). It is also noteworthy that when iron-chlorophyllin is substituted for haem *d* of *Pseudomonas* cytochrome oxidase, the resulting enzyme shows fairly high activity<sup>51</sup>. Thus, there may be very intimate relationships between the prosthetic group of *Pseudomonas* cytochrome oxidase and chlorophylls, on an evolutionary basis. From the evidence already given, I can present diagrammatically a suggestion as to the evolutionary relationships of organisms, as shown in Fig. 3.

Thus, the reactivities of cytochromes *c* with the cytochrome oxidases seem to provide an important key to elucidate events which occurred during evolution.

This work, begun in Osaka University and continued at the University of California, was supported by grants from the U.S. National Institutes of Health and from the U.S. National Science Foundation. I thank Professor M. D. Kamen, Department of Chemistry, Revelle College, University of California, San Diego, California, and Professor K. Okunuki, Department of Biology, Faculty of Science, Osaka University, Japan, for their interest and encouragement. I also thank Dr. S. # Quantum Yield of Ferrocyclochrome *c* Photo-oxidation in Chloroplast Particles

by  
MARTIN SCHWARTZ

Research Institute for Advanced Studies,  
1450 South Rolling Road,  
Baltimore, Maryland

The quantum yield profile of ferrocyclochrome *c* photo-oxidation by chloroplasts subjected to detergent treatment and differential centrifugation appears to represent a partial separation of photosystems into different chlorophyll protein complexes.

THE current hypothesis of two primary photoacts in photosynthesis implies that one photosystem (photosystem I) produces a strong reductant (leading to nicotinamide-adenine dinucleotide phosphate (NADP) reduction) and a weak oxidant, and the other photosystem (photosystem II) produces a weak reductant and a strong oxidant (leading to evolution of oxygen). The two photosystems operate in series, the weak reductant of photosystem II being oxidized by the weak oxidant of photosystem I through an electron transport system involving intermediate electron carriers<sup>1-3</sup>. Abundant evidence indicates that photosystem I is most efficiently sensitized by long wavelength light ( $> 690 \text{ m}\mu$ ) and photosystem II by short wavelength light ( $< 690 \text{ m}\mu$ )<sup>3,4,5</sup>. The two photosystems presumably differ in the composition of their chlorophyll-protein pigment complexes. Accordingly, if it were possible to separate physically a photochemically active particle which contained, for example, only the pigment complex for photosystem I, the action spectrum for a photosystem I assay should reflect this separation when compared with the action spectrum of chloroplasts retaining both photosystems.

Recently, Boardman and Anderson<sup>6,7</sup> separated digitonin treated chloroplasts by differential centrifugation into fractions showing differences with respect to pigment content and photochemical activity. Their results and those from other laboratories<sup>8-10</sup> were interpreted as showing that detergent treated chloroplast particles, the chlorophyll *a/b* ratios of which are increased by the treatment, are "enriched" in the chlorophyll-protein component of photosystem I, whereas particles containing low chlorophyll *a/b* ratios are "enriched" in the pigment component of photosystem II.

The experiments reported here employed preparations of the Boardman-Anderson type and were designed to test whether the quantum yield of photosystem I electron transport activity of these preparations satisfies the requirements for the physical isolation of the pigment complexes of photosystem I imposed by the series hypothesis. The assay chosen for monitoring photosystem I activity was the photo-oxidation of ferrocyclochrome *c* discovered by Nieman and Vennesland<sup>11</sup>. The experiments of Whatley<sup>12</sup> showed that this photo-oxidation reaction was equivalent in these particles to the photoreduction of NADP with the ascorbate-DCIP (dichlorophenol indophenol) couple as the electron donor. Kok *et al.*<sup>13</sup> established the optimum conditions for this reaction by showing that the addition of plastocyanine and a low potential reagent such as methyl viologen ( $E_0' = -0.44 \text{ V}$ ) enhanced the quantum yield of this reaction. They also observed, with detergent treated whole chloroplasts, a long wavelength rise in the quantum yield of ferrocyclochrome *c* photo-oxidation, which indicated photosystem I activity<sup>14</sup>.

Spinach chloroplasts (0.5 mg Chl./ml.), prepared in a *tris*-sucrose medium pH 7.6 as described previously<sup>15</sup>, were treated with 0.5 per cent (w/v) digitonin ( $C_d^0$ ). The resulting particles were separated by differential centrifugation as described by Boardman and Anderson<sup>6,7</sup>. Chloroplast pellets were obtained successively from one preparation at 1,000*g* for 10 min, ( $C_d^1$ ); 10,000*g* for 30 min, ( $C_d^{10}$ ); 50,000*g* for 30 min, ( $C_d^{50}$ ); and 144,000*g* for 60 min, ( $C_d^{144}$ ). Chloroplasts were also subjected to sonic oscillations in *tris*-sucrose medium, pH 7.6, and the resulting particles ( $C_s^0$ ) were either treated with digitonin directly ( $C_s^d$ ) or fractionated to obtain a particle which sedimented between 50,000*g* and 144,000*g*. This particle ( $C_{144}^s$ ) was also treated with digitonin ( $C_{144}^{sd}$ ) and was employed directly after dilution in *tris*-sucrose medium to the appropriate chlorophyll concentration. Total chlorophyll concentration and chlorophyll *a/b* ratios were determined according to Arnon's procedure<sup>16</sup>. Ferrocyclochrome *c* photo-oxidation and ferrocyclochrome *c* photoreduction (catalysed by phenazine methosulphate)<sup>17,18</sup> were monitored with the Kok split beam spectrophotometer which allowed for actinic illumination of the sample while recording absorbance changes. The large extinction coefficient of ferrocyclochrome *c* made it possible to monitor low rates of reaction employing thin chloroplast or particle suspensions and low absorbed light intensities. The actinic intensities used for all systems were such that a two-fold increase in intensity yielded an equivalent quantum efficiency of electron flow. Absolute intensities were measured with a bolometer and chloroplast absorption was measured with an integrating sphere<sup>18</sup>.

The data presented in Fig. 1 indicate that the quantum yield ( $\phi$ ) of ferrocyclochrome *c* photo-oxidation for Boardman-Anderson particles attains a constant maximum of 1 electron equivalent per quantum (1 eq/hv) at long wavelengths ( $> 700 \text{ m}\mu$ ). The particle ( $C_d^{144}$ ), which Boardman and Anderson believe to be enriched in the pigment complex of photosystem I, still retains a long wavelength rise in the quantum yield of electron flow rather than the essentially constant  $\phi$  value as a function of wavelength to be expected from a particle containing principally the pigment complex of photosystem I (Fig. 1, curve 4). At short wavelengths ( $< 680 \text{ m}\mu$ ) a constant  $\phi \approx 0.7 \text{ eq/hv}$  is obtained for ferrocyclochrome *c* photo-oxidation (system I). This  $\phi \approx 0.7 \text{ eq/hv}$  is approximately double that of the maximum quantum yield of the Hill reaction activity of normal chloroplasts (system I + II) as measured by ferrocyclochrome *c* photoreduction when assayed at wavelengths shorter than  $680 \text{ m}\mu$  (Fig. 1, curve 1). Surprisingly, these high  $\phi$  values of unity at long wavelengths for photosystem I activity could only be obtained with the reaction mixture of L. P. Vernon

(personal communication) which contained  $\geq 0.1$  molar phosphate ions. Preliminary experiments seemed to point to a specific effect of high phosphate concentration as other reagents such as sucrose, potassium chloride or sodium chloride suppressed the  $\phi$  values by approximately one half.

The wavelength profile of the quantum yield of ferrocytochrome *c* photo-oxidation obtained with the  $C_{144}^{sd}$  particle (Fig. 1, curve 3) also shows a marked long wavelength rise in  $\phi$  values which attains a relatively constant maximum of 0.8 eq/hv. At short wavelengths, however, ( $< 680$  m $\mu$ ),  $\phi$  values for ferrocytochrome *c* oxidation are essentially equal to the  $\phi$  values for ferricytochrome *c* reduction of normal chloroplasts (Fig. 1, curve 1) and approximately 50 per cent of the  $\phi$  values for ferrocytochrome *c* oxidation of the  $C_{144}^d$  particle. A marked difference between the  $C_{144}^{sd}$  particle and the Boardman-Anderson  $C_{144}^d$  particle is that the  $C_{144}^{sd}$  particle shows a chlorophyll *a/b* ratio of 2.8 whereas the  $C_{144}^d$  particle shows an "enriched" *a/b* ratio of 5.2. This relative enrichment of chlorophyll *a* in the  $C_{144}^{sd}$  particle thus appears to reflect an enrichment of photosystem I activity as suggested by Boardman and Anderson.

Fig. 1. Quantum yield profile of ferrocytochrome *c* photo-oxidation and ferricytochrome *c* photoreduction in spinach chloroplasts and detergent treated particles. The standard reaction mixture for the assay of ferricytochrome *c* reduction contained the following components in  $\mu$ moles/2.0 ml.: *tris* hydrochloric acid, pH 7.4, 50; magnesium chloride, 15; potassium phosphate (pH 7.4), 10; adenosine diphosphate, 2.5; sucrose, 40; sodium chloride, 35; phenazine methosulphate, 0.02; and ferricytochrome *c*, 0.05. For the assay of ferrocytochrome *c* photo-oxidation the reaction mixture contained ( $\mu$ moles/2.0 ml.): potassium phosphate (pH 6.8), 300; plastocyanine, 0.012; methyl viologen, 0.1; ferrocytochrome *c* (reduced with hydrogen and palladium asbestos), 0.05; and potassium cyanide, 10. All assays were performed with chloroplasts or particles containing either 2.5 or 5  $\mu$ g chlorophyll total (*a+b*)/ml. The absorbed light intensities were less than 15  $\mu$ Einsteins/min at all actinic wavelengths. Not more than 28 per cent of the incident light intensity was absorbed at any wavelength.

1, Ferricytochrome *c* reduction (Hill reaction) with normal chloroplasts, chlorophyll *a/b* = 2.8. Normal chloroplasts do not photo-oxidize ferrocytochrome *c*. 2, Ferrocytochrome *c* oxidation with 1,000g precipitate from digitonin treated chloroplasts, chlorophyll *a/b* = 2.4 ( $C_{144}^d$ ). 3, Ferrocytochrome *c* oxidation with 144,000g precipitate from sonicated chloroplasts, chlorophyll *a/b* = 2.8 ( $C_{144}^{sd}$ ). 4, Ferrocytochrome *c* oxidation with 144,000g precipitate, chlorophyll *a/b* = 5.2 ( $C_{144}^d$ ).

The low  $\phi$  values for ferrocytochrome *c* photo-oxidation obtained with the  $C_{144}^d$  particle most probably reflect the removal by centrifugation of particles enriched in photosystem I activity. The data (Fig. 1, curve 2) show a long wavelength doubling of the  $\phi$  value of electron flow with the  $C_{144}^d$  fraction, however, which suggests that a part of the pigment complex of photosystem I is retained in this fraction.

The data presented in Table 1 compare the photosystem I activity of the  $C_{144}^d$  particle and  $C_{144}^{sd}$  particles with the activity of digitonin treated chloroplasts ( $C_{144}^d$ ) and sonicated chloroplasts which were subsequently treated with digitonin ( $C_{144}^{sd}$ ). Neither the  $C_{144}^d$  nor the  $C_{144}^{sd}$  preparation was subjected to differential centrifugation but simply diluted to appropriate chlorophyll concentrations and assayed for photosystem I activity by ferrocytochrome *c* photo-oxidation. The  $\phi$  values obtained at 710 and 640 m $\mu$  for the  $C_{144}^d$  and the  $C_{144}^{sd}$  preparations show that sonication of chloroplasts increases photosystem I activity. Why the  $\phi$  values for the  $C_{144}^{sd}$  particle are less than half of the  $C_{144}^d$  particle is not clear (Table 1). The  $C_{144}^{sd}$  particle constitutes approximately 23 per cent of the  $C_{144}^d$  mixed particle system as determined by total chlorophyll recovery in the  $C_{144}^d$  pellet. Perhaps the small particles of the  $C_{144}^{sd}$  fraction are more easily accessible to digitonin action or more easily accessible to binding with the plastocyanine which is required for ferrocytochrome *c* photo-oxidation activity.

Table 1. QUANTUM YIELD OF FERROCYTOCHROME *c* PHOTO-OXIDATION AND FERRICYTOCHROME *c* PHOTOREDUCTION BY CHLOROPLASTS AND DETERGENT TREATED CHLOROPLAST PARTICLES

System	$\phi$ electron equivalents/quantum	
Ferrocytochrome <i>c</i> photo-oxidation	640 m $\mu$	710 m $\mu$
$C_{144}^d$ , Chl <i>a/b</i> = 5.2	0.69	0.96
$C_{144}^{sd}$ , Chl <i>a/b</i> = 2.8	0.35	0.77
$C_{144}^d$ , Chl <i>a/b</i> = 2.8	0.11	0.24
$C_{144}^{sd}$ , Chl <i>a/b</i> = 2.8	0.14	0.36
Ferricytochrome <i>c</i> photoreduction		
Chloroplasts, chlorophyll <i>a/b</i> = 2.8	0.31	0.074
$C_{144}^d$ , Chlorophyll <i>a/b</i> = 2.8	0.11	—
$C_{144}^d$ , Chlorophyll <i>a/b</i> = 2.8	0.17	—

Reaction conditions are described with Fig. 1. All assays were performed with 5  $\mu$ g chlorophyll (*a+b*)/ml. The absorbed intensities were 10.8  $\mu$ Ein/min at 710 m $\mu$  and 0.7  $\mu$ Ein/min at 640 m $\mu$ . The experiments were performed in air.

The data (Fig. 1, Table 1) show that a maximum quantum yield of electron flow for photosystem I activity (photo-oxidation of ferrocytochrome *c*) which approaches the theoretical maximum of 1.0 eq/hv in long wavelength light ( $> 700$  m $\mu$ ) can be obtained. The series proposal predicts a maximum quantum yield of unity for a pure photosystem I reaction if the pigment complex of photosystem I were the only absorbing group. Because the Hill activity of chloroplasts as measured by ferricytochrome *c* reduction (Fig. 1 and Table 1) exhibits  $\phi$  values in long wavelengths ( $> 700$  m $\mu$ ) of approximately 25 per cent of the short wavelength maximum (that is, 640–690 m $\mu$ ), the series formulation predicts that at least 12.5 per cent of long wavelength light must be absorbed by the pigment assembly of photosystem II in normal oxygen evolving chloroplasts. It follows that the maximum  $\phi$  value experimentally attainable for photosystem I activity in normal chloroplasts would be less than 1 eq/hv, approaching 0.87 eq/hv as a maximum. At 710 m $\mu$  we observed  $\phi = 0.24$  eq/hv for photosystem I activity (ferrocytochrome *c* oxidation) with the  $C_{144}^d$  particles and  $\phi = 0.36$  eq/hv with the  $C_{144}^{sd}$  particle (Table 1). These values are well below a maximum of 0.87 eq/hv predicted from the Hill activity data at 710 m $\mu$  (Fig. 1, curve 1). The  $C_{144}^{sd}$  particle which retains the *a/b* ratio of normal chloroplasts does, however, show long wavelength  $\phi$  values of approximately 0.8 eq/hv for photosystem I activity (Table 1). Whether the difference between this maximum

Table 2. REDUCTION OF NADP BY CHLOROPLAST PARTICLES AND DIGITONIN TREATED CHLOROPLAST PARTICLES

System	$\phi$ electron equivalents/quantum	
	640 m $\mu$	710 m $\mu$
C <sub>144</sub> <sup>s</sup> , + DCIP	0.12	0.37
C <sub>144</sub> <sup>s</sup> , - DCIP	0	~0.04
C <sub>144</sub> <sup>sd</sup> , + DCIP	0.18	0.49
C <sub>144</sub> <sup>sd</sup> , - DCIP	0.18	0.49

The standard reaction mixture contains the following components in  $\mu$ moles/2.0 ml.: potassium phosphate (pH 6.8), 300; sodium ascorbate, 10; plastocyanine, 0.012; ferredoxin, transhydrogenase, and NADP, 1.0; 3-(3,4-dichlorophenyl)-1,1-dimethylurea, 0.002; and dichlorophenol indophenol (DCIP), 25 (where indicated). All assays were performed with 5  $\mu$ g chlorophyll ( $a+b$ )/ml. The absorbed intensities were 10.3 m $\mu$ E/m at 710 m $\mu$  and 9.7 m $\mu$ E/m at 640 m $\mu$ . The experiment was performed in argon.

$\phi = 0.8$  eq/h $\nu$  and the maximum  $\phi = 1.0$  eq/h $\nu$  for the C<sub>144</sub><sup>d</sup> particle is fortuitous or reflects the difference in the concentration of the system II pigment complex retained by the respective particles is unresolved.

Table 2 presents data obtained in an attempt to equate  $\phi$  values for NADP reduction with ferrocytochrome *c* oxidation. A comparison was made for NADP reduction activity with the C<sub>144</sub><sup>s</sup> and the C<sub>144</sub><sup>sd</sup> particles when supplied with the ascorbate DCIP couple. As shown in Table 2 the quantum yield of NADP reduction at rate-limiting light intensities is greater after treatment of the C<sub>144</sub><sup>s</sup> particle with digitonin (C<sub>144</sub><sup>sd</sup>). It is to be noted that at low light intensities NADP reduction with the C<sub>144</sub><sup>sd</sup> particle requires the ascorbate-plastocyanine couple whereas the C<sub>144</sub><sup>s</sup> particle requires DCIP. Why the absolute  $\phi$

values for NADP reduction are poorer than those for ferrocytochrome *c* oxidation is not resolved (compare Tables 1 and 2).

I thank Mr. G. A. Ebert for his excellent assistance and also Dr. B. Kok for useful discussion.

This work was supported in part by a contract with the U.S. Office of Naval Research.

## Catecholamine Metabolism in Schizophrenia

by

G. L. MATTOK  
D. L. WILSON  
A. HOFFER

Psychiatric Research Unit, University Hospital,  
Saskatoon, Saskatchewan

Significant differences have been found between the concentrations of free dopamine excreted in the urine of normal individuals and schizophrenic patients.

EVIDENCE suggests that there is a relationship between the metabolism of catecholamines and mental illness<sup>1,2</sup>. Although no definite relation has been established, several theories which relate aberrations in the metabolism of these compounds and schizophrenia have been proposed. In 1954, Hoffer, Osmond and Smythies<sup>3</sup> suggested that the symptoms of schizophrenia result from the abnormal metabolism of adrenaline to adrenochrome and, in turn, adrenolutin. Osmond and Smythies<sup>4</sup> had earlier proposed that schizophrenia results from an abnormal methylation reaction of the catecholamines. More recently, Friedhoff and Van Winkle<sup>5,6</sup> have reported a correlation between the incidence of dimethoxyphenylethylamine in urine and schizophrenia; however, several groups have not been able to confirm this relationship (compare ref. 7).

Recently a spectrophotometric method for the differential estimation of adrenaline, noradrenaline, dopamine, metanephrine and normetanephrine in one urine sample was described<sup>8</sup>. While it was possible to assay only one or two of the biogenic amines in a urine sample, no other approach to the interpretation of the results than a direct comparison of the concentrations of amines was possible. When the concentrations of five of the major biogenic amines, together with their conjugates, are obtained at one time, then it becomes possible to consider

the dynamic aspects of catecholamine metabolism. The application of such an approach to the interpretation of the concentrations of urinary amines in schizophrenia forms the basis of the present article.

Overnight urines were used and the period of the collection recorded. Urines were obtained from acute schizophrenics who were patients in University Hospital, Saskatoon\*, and the normal controls were members of the staff of the Psychiatric Research Unit. The concentrations of free and conjugated adrenaline, noradrenaline, dopamine, metanephrine and normetanephrine were estimated by the method of Mattok *et al.*<sup>8</sup>.

The concentrations of the amines were estimated in urines from twenty-four normal controls and twenty-two acute schizophrenics. Statistical analyses were made using the Mann-Whitney *U* test<sup>9</sup>. Because we did not attempt to predict the direction of the differences in the concentrations of the amines, we calculated two-tailed probabilities for each amine; these values are given in Table 1. The median values of the concentration of each amine assayed are also given in Table 1.

\* University Hospital, Saskatoon, is an active treatment centre. Psychiatric patients participate in a normal amount of physical activity and are maintained on a normal diet. The average length of time which psychiatric patients stay at this hospital is 19 days.

The initial stages in the metabolism of the catecholamines can be represented by the following scheme:

Scheme I.

where X, Y and Z represent the products of unspecified abnormal processes and the precursors are dopamine, noradrenaline and adrenaline, respectively. For the sake of brevity, possible deviations at other stages have not been included. Some alternative pathways which may be associated with schizophrenia, and which would be included by scheme I are: (i) the oxidative melanization of dopamine; (ii) the oxidation of adrenaline to adrenochrome<sup>8</sup>; and (iii) the di-O-methylation of dopamine to dimethoxyphenylethylamine<sup>5,6</sup>.

Table 1. BIOGENIC AMINE EXCRETION FOR NORMAL CONTROL AND SCHIZOPHRENIC SUBJECTS

Amine	Median concentrations in urine and p factors			Conjugated amine excretion*		
	N	S	P	N	S	P
Dopamine	10.3	5.3	0.0028	15.4	18.6	0.5552

Adrenaline	<0.02	<0.02	0.3898	<0.02	<0.02	0.2420
Normetanephrine	9.0	10.1	0.5532	5.8	6.4	0.8494
Metanephrine	1.6	0.4	0.1600	0.9	2.3	0.0478

N, Normal subjects; S, schizophrenic subjects; P, two-tailed probability.

In general, attempts to correlate the concentrations of biogenic amines with pathological or psychiatric disorders have been based on the absolute concentrations of one or two of the amines and expressed as  $\mu\text{g/h}$  or  $\mu\text{g/mg}$  of creatinine. The usefulness of the creatinine scale has been seriously challenged by Pscheidt *et al.*<sup>10</sup>, who have found that variability in creatinine output is common among mental patients; indeed, a significant correlation may exist between such variations and psychotic status. Some disorders, such as pheochromocytoma, which result in marked elevations of the concentrations of some urinary amines, may be satisfactorily confirmed by measurements of the absolute concentrations of some of the amines present in the urine. An abnormal concentration, however, does not in itself provide any information about the nature of the abnormal reaction or the point at which it first occurs in the metabolic sequence. This kind of information can only be obtained from a consideration of the discriminating features of the metabolic picture in relation to the precursors and metabolites. A given concentration of an amine could result from any of several factors, some of which may not result in an overall harmful effect. For example, a low dopamine concentration could be the result of: (1) synthesis of less than normal amounts of a precursor because of a defective mechanism at some remote stage in the synthesis of dopamine; (2) less than normal decarboxylation of dihydroxyphenylalanine (DOPA); (3) normal formation of dopamine by (2), but subsequently largely conjugated; (4) greater than normal  $\beta$ -hydroxylation of dopamine to form noradrenaline; (5) further metabolism of dopamine by an abnormal process (that is, to form X).

A statistical comparison of the analyses obtained with urines from twenty-four normal controls and twenty-two schizophrenic patients showed that the difference in concentrations of free dopamine in the two groups is highly significant (see Table 1). The median value for urinary free dopamine in the control group was  $10.3 \mu\text{g/h}$  and in the schizophrenic group it was  $5.3 \mu\text{g/h}$ . There is also a significant difference in the concentrations of conjugated metanephrine in the two groups.

Because there are no major quantitative differences in the concentration of dopamine metabolites in normal and schizophrenic subjects, it is likely that normal amounts of dopamine are initially synthesized in schizophrenics. The lower concentrations of free dopamine in schizophrenia are therefore probably the result of increased  $\beta$ -hydroxylation of dopamine (which may arise from a reduction in dopamine binding capacity, thereby increasing the amount of dopamine available for further metabolism), or the intrusion of an abnormal reaction. Alternatively, there may be augmentation of a normally relatively minor pathway in the metabolism of dopamine. An interpretation based on an abnormal metabolic reaction of dopamine, however, would not account for the increased conjugation of metanephrine. Because it is unlikely that two independent aberrations would occur in these two interdependent reactions, the differences in the concentrations of free dopamine and conjugated metanephrine can be assumed to be related. This would be so if there were increased metabolism of dopamine to noradrenaline in schizophrenia. The synthesis of greater than normal amounts of noradrenaline would mean, in turn, greater opportunity for the synthesis of adrenaline and would therefore not necessarily be reflected by urinary concentrations of noradrenaline greater than normal. If abnormally large amounts of adrenaline are synthesized in schizophrenia this would lead to increased conjugation of the biogenic amines, thereby reducing the possibility of the existence of toxic concentrations. The statistical analysis showed, however, no significant difference in the concentrations of total adrenaline (that is, free and conjugated adrenaline and metanephrine) for normal and schizophrenic subjects. The excess (that is, relative to normal) adrenaline synthesized is probably, therefore, metabolized by an abnormal reaction not accounted for by the assay.

The present results therefore indicate that dopamine is synthesized normally in schizophrenia, but is metabolized to give abnormally high concentrations of noradrenaline and, in turn, adrenaline. The increased concentrations of adrenaline may stimulate the processes leading to conjugation and complete detoxification of metanephrine. Because the raised concentrations of adrenaline must be rapidly reduced to more normal concentrations, some of the excess adrenaline is probably removed by an abnormal process.

We thank members of the clinical and nursing staff of the Psychiatric Research Unit for their co-operation in obtaining the urine samples. This work was supported by grants from the Department of Public Health (Saskatchewan) and the Department of National Health and Welfare (Ottawa).

## Effect of Feeding Calcium Cyclamate to Rats

by

P. O. NEES

PHILIP H. DERSE

Wisconsin Alumni Research Foundation,  
Madison, Wisconsin

Calcium cyclamate (cyclohexyl calcium sulphamate) is present as a sweetener in a number of soft drinks. When it is fed to rats over a long period it can decrease the rate of growth, possibly by affecting the adrenals.

IN recent years the use of artificial sweeteners has increased significantly. The U.S. Department of Agriculture<sup>1</sup> reported that the consumption of sweeteners in 1964 was twice that in 1963 and five times that in 1959. The major part is consumed in drinks containing calcium cyclamate (cyclohexyl calcium sulphamate).

Persons drinking these beverages can take as much as 1 per cent cyclamate in their daily diet. For example, three bottles of soft drinks can contain a total of 4 g of calcium cyclamate. This amount, consumed daily with a normal food intake (400 g dry weight, 2,400 calories) would result in a diet containing 1 per cent calcium cyclamate. Other sources of calcium cyclamate may further increase the proportion of cyclamate in the diet.

Fitzhugh *et al.*<sup>2</sup> fed cyclamate concentrations as high as 5 per cent in the diet to rats for 2 years. No effects were observed with less than 1 per cent sodium cyclamate in the diet. A decrease in the rate of gain was observed at levels of 1 and 5 per cent in the diet. 5 per cent cyclamate caused moderate diarrhoea. Histopathologically, the animals showed no abnormalities.

Richards *et al.*<sup>3</sup> carried out experiments involving feeding cats and dogs with diets containing 0.05, 0.1 and 1 per cent sodium cyclamate. They reported that the body weight of rats receiving 0.1 and 1 per cent sodium cyclamate in the diet tended to remain below that of the control rats. No other pharmacological reactions were noticed. The excretion and distribution of cyclamate labelled with sulphur-35 were studied by Taylor *et al.*<sup>4</sup> 95 per cent of the cyclamate was excreted in the urine and faeces. Small amounts of sulphur-35 were found in all tissues, including the foetus.

The work reported here was carried out using calcium cyclamate, which is now more commonly used as a sweetener than is the sodium salt. Higher levels of cyclamate were used to allow a clearer interpolation to those amounts presently obtained in the daily human dietary. The use of calcium cyclamate in human diet to reduce the caloric intake led us to include feeding trials in which the caloric intake was restricted.

Weanling Sprague-Dawley rats were divided into three groups, twenty-six males and twenty-six females in each group. The animals were housed individually in cages with screen bottoms and given water *ad libitum*. During the first 8 weeks of the experiments all the animals in each group received their respective diets *ad libitum*.

Group 1 rats were fed only on a commercial ground diet containing a minimum of 23.0 per cent crude protein, 4.5 per cent crude fat, a maximum of 6.0 per cent crude fibre, and a maximum of 9.0 per cent ash. Group 2 were given 5 per cent calcium cyclamate in the basal diet; and group 3, 10 per cent.

After 8 weeks on test diets the separate groups were divided into two sections. Rats in section A continued

to receive their respective diets *ad libitum*. Rats in section B received their respective diets at a level equivalent to 60 per cent of the consumption of section A rats of the same group.

In addition to limiting the amount consumed, five females from each section were mated with males from their respective sections, transferred to breeding cages and maintained on the same diet schedule as the non-reproduction animals. Animals with young were allowed to raise them to weaning. After a reasonable rest the females were remated and allowed to raise their young to weaning. After the second litters were weaned, the females were returned to standard screen bottom cages until week 52 when all remaining animals were killed.

Each animal was weighed and its food consumption recorded each week. At selected intervals the individual daily consumption of water was determined on five males and five females from each section of each group. At 6, 9 and 12 months blood and urine analyses were conducted on a representative portion of the animals from each section.

At 90 days two males and two females from each section of each group were killed and examined for gross and histological alterations. At 6 months, three males and three females from each section of group 1 (negative control) and group 3 (10 per cent calcium cyclamate) were killed and similarly examined. At the end of the study all animals were killed and examined.

At 40 weeks, three males and three females from each section of each group were placed in metabolism cages for 3 days. During this period food consumption and faecal and urine excretion were measured. Urine and faeces were analysed to determine nitrogen and calories excreted. Intake and excretion data were then compared to determine amount of nitrogen and calories retained.

The body weights (Figs. 1 and 2) show that the gains in body weight of animals receiving 10 per cent calcium cyclamate were approximately 80–85 per cent of the weight gains noted for animals of the control group. Animals receiving 5 per cent calcium cyclamate gained approximately 85–90 per cent as much weight as the control animals. This difference was apparent throughout the test period and the differences were similar whether limited or *ad libitum* fed groups were compared.

Figs. 3 and 4 give the food consumption converted to basal diet alone, thereby eliminating the quantity of non-caloric calcium cyclamate in the diet. The data show that group 1 (negative control) and group 3 (10 per cent calcium cyclamate) consume essentially equal quantities of basal diet. On the basis of basal diet alone, group 2 animals (5 per cent calcium cyclamate) consumed approximately 7 per cent less than group 1 animals.

Water consumption (Table 1) is significantly increased in animals receiving calcium cyclamate. Addi-

tional water measurements, made periodically during the experiment, also showed this.

The results of the balance studies were calculated on the basis of two assumptions. In one calculation it was assumed that all the calcium cyclamate was excreted in the urine and in the other that all the cyclamate was in the faeces. It is known that calcium cyclamate is excreted by way of urine and faeces, but adequate analytical procedures are not available, and the exact quantity excreted cannot be determined. The available values indicate that animals receiving calcium cyclamate utilized both nitrogen and calories in the feed as well as or better than the animals in the negative control group.

The results of the first litter reproduction study (Table 2) indicated that animals receiving limited ration conceived but were unable to raise their young beyond 5 days.

Animals receiving feed *ad lib.* conceived and were able to raise their young to weaning (21 days). Control weanling rats weighed 42 g and 10 per cent cyclamate weanling rats averaged 50 g in weight; 5 per cent cyclamate weanling rats weighed 32 g.

The results of the second litter reproduction study (Table 3) showed the control animals (limited feeding)

Fig. 1. Average body weight of male rats plotted against time. x, Basal ration; O, 5 per cent calcium cyclamate; □, 10 per cent calcium cyclamate; —, fed *ad lib.*; ---, fed limited diet.

Fig. 2. Average body weight of female rats plotted against time. x, Basal ration; O, 5 per cent calcium cyclamate; □, 10 per cent calcium cyclamate; —, fed *ad lib.*; ---, fed limited diet.

and animals receiving 5 per cent cyclamate (limited feeding) conceived, but that all their young died in 7 days. Animals receiving 10 per cent cyclamate (limited feeding) did not conceive.

Animals receiving feed *ad lib.* conceived and again raised their young to weaning (21 days). Control weanling rats averaged 52 g in weight, 5 per cent cyclamate weanling rats averaged 45 g and 10 per cent cyclamate weanling rats averaged 33 g in weight.

Clinical laboratory examinations showed no remarkable variation between the haematological data of test groups and the negative control groups until the terminal examination, in which a decrease in white cell counts was found in male rats receiving 10 per cent calcium cyclamate *ad libitum*. The nitrogen content of the urine is higher in rats receiving feed *ad libitum* than in rats receiving feed on a limited basis. After 9 months there was an indication that animals receiving the diet containing 10 per cent calcium cyclamate *ad libitum* have significantly higher levels of urine nitrogen than animals receiving the basal diet *ad libitum* (group 1). This was not the case at 12 months.

The animals showed no gross evidence of toxicity nor undesirable results of feeding calcium cyclamate other than loss of weight. The faeces from animals receiving calcium cyclamate were soft, and contained more moisture. At times this condition approached diarrhoea in the animals receiving 10 per cent calcium cyclamate, while faeces from animals receiving 5 per cent calcium cyclamate generally consisted of larger pellets with a higher water

content. The faecal changes were most marked during the first 8 weeks. The urine of the control animals was found to be different from that of the test animals when allowed to evaporate to dryness. Urine from animals receiving calcium cyclamate left an excessive crystalline residue which was not present in urine from control animals.

The organs of all the animals killed at 1 year were weighed and body weight ratios calculated. The organs weighed were the heart, liver, spleen, kidney, gonads, adrenal and thyroid. Tables 4 and 5 show the average weights of the organs and the percentage of body weight of the *ad libitum* animals and the limited fed animals respectively.

The values for adrenal weights as a percentage of body weights were compared statistically.

The following conclusions can be made with reasonable confidence: (1) The weights of the adrenals of both male and female rats fed 10 per cent calcium cyclamate increased under both feeding regimes. The increase is more marked under limited feeding conditions. (2) The adrenals of male rats fed 5 per cent calcium cyclamate under limited feeding conditions increased in proportion

to the rest of the body, but this did not occur when the same ration was fed *ad lib.* The weights are significantly higher than those of the control males and significantly lower than those male rats fed 10 per cent calcium cyclamate. (3) Female rats fed 5 per cent calcium cyclamate did not show this rise in relative adrenal weight under any conditions.

Histologically, the tissues of rats fed calcium cyclamate showed changes in the testes, adrenals, kidneys and pancreas. The testes of rats fed cyclamate show an increased incidence and severity of atrophy and degeneration of the seminiferous tubules compared with those of control rats. A few atrophic tubules were noted in sections of testes from control rats, and the changes noted in test animals may be an aggravation of a normal ageing process. Severe atrophy of the seminiferous element of the testes was found as early as 6 months in tissue from one rat fed 10 per cent cyclamate. The adrenals of the test rats showed primarily cortical changes. There were subtle alterations of the appearance of the zones in the test rats. In the adrenals of animals fed 10 per cent calcium cyclamate the outer zone of the cortex (zona granulosa) was pale on staining, the cells contained increased cytoplasm and the nucleus was lighter than in controls. The demarcation between the outer zona granulosa and the zona fasciculata was poorly defined. In the adrenals from control animals, cells from the outer zone were more tightly packed and contained a more darkly staining nucleus, growing a darker, better defined zona granulosa. This was particularly evident in tissues from the control female rats. Changes in the appearance of the adrenals were clearer in the females than in the males. The appearance of the kidneys was altered more frequently in animals fed calcium cyclamate than in animals on the basal diet. Concretions were frequently found in or near the renal pelvis. Focal pancreatic atrophy was also more marked in test tissues than in control tissues.

Comparing data on body weight gain and food consumption it is clear that, on the basis of the quantity of basal diet consumed, the calorie intake of the control rats and the rats receiving 10 per cent calcium cyclamate is essentially equal. Also, the 7 per cent decrease in the calorie intake of rats receiving 5 per cent calcium cyclamate compared with the intake of control rats is not equal to the 15 per cent decrease when the weight gains of these same groups are compared. The lack of gain in weight in test animals compared with the control animals cannot be explained by calorie limitations. Calculations of feed efficiencies based on the amount of basal diet consumed also show that animals fed calcium cyclamate utilized the food less well than animals on the basal diet alone. This inability to make effective use of the food was not evident in the calorie and nitrogen balance studies. Examination of the percentage basal nitrogen and percentage basal calories retained shows that the test animals absorb and utilize approximately the same percentage of the calories consumed. The nitrogen retained from the diet was higher for the test groups than for the controls. The possible loss of nutrients as a result of loose stools is therefore small, and is not a major factor in the low weight gain of test animals. These results indicate that nutrients are utilized by animals fed calcium cyclamate in a manner different from that of control animals. These differences may be the result of any one or several effects of calcium cyclamate, including increased metabolic rate, direct interference with cellular utilization of nutrients, and energy utilized to metabolize and/or excrete calcium cyclamate or its metabolites.

The variation in water consumption seems to be a compensation for the increased excretion of water in the faeces of the animals fed calcium cyclamate. Measurements of the total water excreted from urine and faeces do not, however, account for the increased water intake, indicating an increased loss of water from respiration and skin surfaces.

Examination of the urine shows that there is some alteration in kidney excretion. The increased crystalline residue in the urine from animals receiving calcium cyclamate shows that the test material or its metabolites was excreted through the kidney. The variations in urine nitrogen concentrations after 9 months cannot be explained by nitrogen from the calcium cyclamate.

The reproduction experiments involved only small numbers of animals, but essentially the same results were obtained when the experiment was repeated. The relation between the levels of cyclamate administered in these experiments to possible levels consumed by the pregnant or lactating human is not clear. Certainly the effect of nutrition or the effect of curtailment of the growth of the young animal is important. This type of reduction of growth rate is known to be capable of impairing aptitude and accomplishment.

Also, despite the small number of animals observed, the number of young born to each female was reduced when calcium cyclamate was incorporated in the diet. Further experiments have been carried out to confirm this and will be reported later.

The results show a significant increase in adrenal weight in rats fed calcium cyclamate which is more striking when expressed as a percentage of body weight. This indicates an effect either directly on the adrenal or indirectly, possibly by way of the pituitary. We immediately felt that some mechanism was causing an increase in metabolic rate. Preliminary experiments with these animals showed an increase in the uptake of iodine-125, increased consumption of oxygen, change in heart rate, increased irritability, and increased respiration, all indicating an alteration in metabolism.

Tables 4 and 5, which tabulate organ weights, show that as the weight of the animal is reduced, the weights of the heart, liver, spleen and kidneys vary directly with the weight of the animals. In the case of the endocrine organs (gonads, adrenals, and thyroid), however, the organ weights remain the same and the percentage of body weight occupied by these organs increases in the smaller animals.

Histological examination and observations appear to support the results of measuring organ weight in indicating an effect on the testes and the adrenals as a result of feeding calcium cyclamate for 1 year. Because of the significant difference in adrenal weight between test and control groups, the adrenal glands were examined closely for slight changes that could explain the apparent weight variation. The subtle changes in the zones may indicate a tendency to hypoplasia of the zona granulosa of the adrenal in the control animals and a tendency to hyperplasia of the zona granulosa of the adrenals in the test animals. This might explain the increased adrenal gland weights in test animals.

The increased weight of the testes does not appear to result from stimulation of any particular element in testicular tissue, but is probably a general stimulation resulting in increased testicular weight in most cases but occasionally resulting in severe degeneration and necrosis of the seminiferous tubules.

The higher incidence of calcified concretions in kidneys of animals receiving calcium cyclamate may result from an increased intake of calcium from the cyclamate salt or might occur because the comparatively high level of cyclamate salt in the urine changed the solubility of other urine components. The pancreatic changes noted were not unusual for tissues from 1 year old animals.

The results described here indicate that cyclamate has a positive metabolic effect, but these effects appear transitory or take effect only during the time the animals are consuming a diet containing calcium cyclamate. The time of day at which the experiments are conducted is important. The rat is a nocturnal animal, and it consumes most of its food during the night. That the effect on rats receiving calcium cyclamate in the diet is possibly transitory and that its effect may be metabolic necessitate further consideration. Carswell *et al.*<sup>5</sup> have studied *cyclohexylamine*, a possible metabolite of cyclamate, and its properties as a strong base. Audieth and Sveda<sup>6</sup> in their original article on the preparation of the cyclamates draw attention to the properties of *N*-substituted sulphonic acids. Swanson<sup>7,8</sup> compares the action of many aliphatic

amines. Initial excretion work with rats receiving calcium cyclamate shows that the material does break down.

## Effect of Anti-rat Lymphocyte Antibody on Humoral Antibody Formation

by

K. JAMES

N. F. ANDERSON

Department of Surgical Science and Medical Research Council Research Group on Clinical and Experimental Problems of Transplantation, The Medical School, Edinburgh, Scotland

Injections of rabbit and horse anti-lymphocytic sera into hooded rats inhibited the primary humoral antibody response to sheep erythrocytes, but did not have a marked effect on the secondary response. The major part of the immunosuppressive activity was associated with the IgG fraction. Antibody fragments were not effective in suppressing the immune reaction.

INTEREST in the immunosuppressive properties of anti-lymphocytic serum has been stimulated by the observations of Woodruff and Anderson<sup>1,2</sup> that the survival of skin homografts in rats can be greatly prolonged if the recipients are treated with rabbit anti-rat lymphocyte serum (ALS). More recent investigations have revealed that administration of anti-lymphocytic serum can also prolong the survival of skin homografts in mice<sup>3,4</sup> and renal homotransplants in dogs<sup>5,6</sup>, and it appears that anti-human lymphocyte sera may be of therapeutic value in the transplantation of human organs<sup>7</sup>.

Because of the potential practical importance of these observations we have investigated the effect of anti-lymphocytic antibody, and of fragments thereof, on the humoral antibody response of rats to sheep erythrocytes. These investigations were carried out to assess the potency of fractionated anti-lymphocytic serum and in order to obtain further data on the mode of action of this material. Similar investigations have recently been reported in mice using unfractionated antiserum<sup>8</sup>.

The anti-lymphocytic sera used were produced in a horse and in rabbits by the injection of thoracic duct lymphocytes obtained by cannulation of hooded strain male rats. The horse received intravenous injections weekly for 3 weeks and was given a fourth injection 2 weeks later. Each injection contained  $1.07\text{--}1.3 \times 10^9$  lymphocytes ( $> 95$  per cent viable). The horse was exsanguinated 10 days after the last injection. The rabbits received a total of three intraperitoneal injections, each containing  $2 \times 10^8$  lymphocytes at weekly intervals, and were bled 10 days after the final injection. Further bleedings were per-

formed on the rabbits 10 days after re-injection intraperitoneally with from  $1$  to  $2 \times 10^8$  lymphocytes.

'Sephadex G200' gel filtration and reduction with mercaptoethanol (0.2 moles/l.), followed by alkylation, revealed that the antibody produced in horses was distributed in both the 19S and 7S fractions of serum, while the rabbit antibody was predominantly 7S protein. Because of the difficulty of preparing horse antiserum free from rat erythrocyte agglutinin activity, most of this work was performed with a preparation of IgG globulin which was almost devoid of this activity (see Table 1). The limited supply of rabbit antisera prevented extensive work with fractionated material.

The IgG preparation from the horse anti-lymphocytic serum was obtained by repeated (twice) sodium sulphate precipitation (the final concentration of the sodium sulphate was 14 per cent w/v) followed by diethylaminoethyl (DEAE) cellulose batch chromatography on Whatman DE11 exchanger with a capacity of 1.0 m.equiv./g (ref. 8). The product was concentrated by lyophilization and reconstituted in phosphate buffered saline (pH 7.2, 0.06 molar phosphate containing 0.15 molar sodium chloride). Immuno-electrophoretic analysis, using a rabbit anti-horse serum and polyacrylamide gel electrophoresis, indicated that the preparation contained only small amounts of contaminating protein (probably IgT).

The F(ab')<sub>2</sub> portion of the antibody molecule, which contains both antibody combining sites, was obtained by digestion with pepsin<sup>9</sup> at 37° C for 48 h in 0.1 molar acetate buffer, pH 4.0, using 2 mg enzyme for each 100 mg of protein. Degradation of the IgG to the F(ab')<sub>2</sub> product

Table 1. PROPERTIES OF ANTISERA AND ANTIBODY PREPARATIONS

Sample	Protein conc. (g per cent)	Reciprocal titres			Effect on primary response
		Lymphocyte agglutination	Lympho-cytotoxic	Erythrocyte agglutination	
(1) Horse ALS inactivated and absorbed with one volume rat erythrocytes	5.0 (1 g per cent IgG)	512	512	128	Suppression
(2) IgG globulin from horse ALS	1.0	64	256	< 2	Suppression
(3) F(ab') <sub>2</sub> —pepsin digest from 2	1.0	32	8	4	No effect
(4) Fab'—reduced and alkylated sample from 3	1.0	4	8	< 2	No effect
(5) IgG globulin from normal horse serum	1.0	< 2	8	< 2	No effect
(6) Rabbit ALS inactivated and absorbed with a half volume of rat erythrocytes	5.3	512	512	2	Suppression
(7) Normal rabbit serum inactivated	4.9	< 8	< 8	4	Partial suppression

Note: These results are from duplicate assays.

was shown to be complete by immunodiffusion and subsequent cytotoxic analyses (see Table 1). A sample of this material was reduced with 0.1 molar cysteine hydrochloride and alkylated by dialysis against 100 volumes of the phosphate buffered saline containing iodoacetamide (0.02 moles/l.). The univalent antibody fragment obtained (Fab') did not agglutinate lymphocytes *in vitro*, indicating complete reduction (Table 1). Both these preparations were finally equilibrated against phosphate buffered saline as already described.

Erythrocyte agglutinin activity was determined in  $3 \times \frac{1}{2}$  in. test-tubes by adding 0.1 ml. of 2.5 per cent (v/v) erythrocytes to 0.25 ml. volumes of doubling dilutions of the test sample. All dilutions were performed in the phosphate buffered saline used previously. After incubation for 18 h at room temperature (20° C) the contents of the tubes were agitated and then examined macroscopically and microscopically.

Test sera failing to agglutinate sheep erythrocytes were examined for antibodies by the Coombs (anti-globulin technique) using a rabbit anti-rat serum. The non-agglutinating rat sera were incubated with sheep erythrocytes, as in the standard test, after which they were washed (three times) with 3 ml. volumes of phosphate buffered saline. After this the sheep erythrocytes were resuspended in 0.5 ml. of the phosphate buffer and divided into two equal portions. To one sample was added one drop of the rabbit anti-rat serum and to the other one drop of normal rabbit serum. Both sera had been inactivated (56° C for 30 min) and absorbed with equal volumes of sheep erythrocytes. Controls were also performed using normal sheep erythrocytes. The tubes were examined macroscopically after 3 h at room temperature.

formation was achieved only with whole antisera and intact IgG antibody. It should be noted that these samples alone exhibited lymphocytotoxic activity as assayed by *in vivo* and *in vitro* procedures. The preparation of IgG, however, demonstrated only weak cytotoxic activity *in vivo*.

The lymphopenia produced by rabbit antibody was more marked and prolonged than that observed with the horse antiserum. Furthermore, the Coombs anti-globulin test indicated that a greater agglutination was achieved with the rabbit antibody. All the sheep erythrocytes treated with the non-agglutinating sera from rats receiving horse anti-lymphocytic antibody were strongly agglutinated by the rabbit anti-rat serum. In contrast, of the sheep erythrocytes treated with the eleven negative sera from rats receiving the rabbit anti-lymphocytic antibody, only two were agglutinated by the rabbit anti-rat serum. Thus it would seem that rats treated with the horse antibody possessed appreciable amounts of non-agglutinating erythrocyte antibody while this was only rarely detected in rats receiving the more effective rabbit antibody.

The divalent antibody fragment (F(ab')<sub>2</sub>) agglutinated lymphocytes *in vitro* but failed to suppress humoral antibody formation. Thus degradation of the Fc (the complement and cell surface binding) portion of the molecule, with the expected loss of cytotoxic activity, also destroys the immunosuppressive properties of this antibody. The univalent moiety (Fab') did not agglutinate or lyse the lymphocytes *in vitro*, nor did it inhibit antibody formation. Nevertheless, this material was shown by the Coombs technique, using a rabbit anti-horse IgG, to bind to lymphocytes *in vitro*.

Table 2. EFFECT OF ANTI-LYMPHOCYTE ANTIBODY AND ANTIBODY FRAGMENTS ON THE PRIMARY RESPONSE OF RATS TO SHEEP ERYTHROCYTES

Nos. of rats	Treatment	Lymphocyte count day*		Reciprocal erythrocyte agglutination titre											Day of test	Effect on primary response
		-3	0	<2	2	4	8	16	32	64	128	256	512	1,024		
12	No pretreatment			—	—	—	—	—	3	1	4	1	2	1	5	No effect
8	Horse ALS	5,910 (100)	2,180 (37)	6	2	—	—	1	5	4	1	—	—	1	10	Suppression
14	1 g% IgG from horse ALS	5,100 (100)	3,810 (75)	7	—	4	1	2	—	—	—	—	—	—	5	Suppression
8	1 g% F(ab') <sub>2</sub> from above	5,240 (100)	5,320 (101.5)	—	—	—	—	—	—	2	6	—	—	—	10	No effect
10	1 g% Fab' from above	—	7,190	—	—	—	—	1	3	2	4	—	—	—	5	No effect
8	1 g% normal horse IgG	5,600 (100)	4,950 (88.4)	—	—	1	2	—	2	2	3	—	3	—	5	No effect
24	1 g% IgG from horse ALS to 13,560 Wistar rats (line bred)	13,560 (100)	8,860 (65.3)	—	—	—	—	—	—	3	5	15	1	—	5	No effect
4	1 g% IgG from horse ALS to 10,510 Wistar rats (inbred)	10,510 (100)	9,430 (89.7)	—	—	—	1	2	1	3	—	—	—	—	10	No effect
12	Rabbit ALS	5,910 (100)	780 (13.2)	11	—	—	1	—	—	—	—	—	—	—	5	Suppression
6	Normal rabbit serum	5,380 (100)	4,920 (91.5)	—	—	1	3	1	2	1	—	—	—	—	5	Partial suppression

Each animal received 2 ml. of test sample intraperitoneally on days -3, -2 and -1 and was injected (intravenously) with  $1 \times 10^6$  erythrocytes in 1 ml. on day 0.

\* The figures given in parentheses are per cent values based on day -3 count = 100 per cent.

Note: All experiments were performed with hooded rats except where otherwise indicated.

Lymphocyte agglutinins and lymphocytotoxins were determined by procedures described previously<sup>10</sup>. The *in vivo* cytotoxicity of the preparations was assayed by determining their effect on the peripheral blood lymphocyte count.

In most of the experiments, equal numbers of hooded male (210–275 g) and female rats (155–215 g) were used. The quantities of materials administered are indicated in Tables 1–3. A few results obtained with two strains of Wistar rats (one line bred, the other inbred) have also been included in Table 2.

Detailed preliminary investigations revealed that the peak day of primary response in hooded rats to sheep erythrocytes was day 5, and so, in all subsequent analysis of effect on the primary responses, the sera were usually examined on day 5 and day 10. The rat sera were examined 5 days after secondary challenge.

It can be seen from Tables 1 and 2 that effective suppression of humoral antibody (erythrocyte agglutinin)

The preparation of horse antibody IgG to hooded rat lymphocytes failed to inhibit the production of erythrocyte agglutinin in the two other strains of rats tested even though it produced a lymphopenia similar to that observed in the hooded rat. This could be due to a number of factors including the larger size of these animals (260–355 g), their higher initial lymphocyte count and a degree of strain specificity.

The effect of rabbit and horse anti-lymphocytic antibody on the secondary response of hooded rats to sheep erythrocytes can be seen in Table 3. Although only small numbers of rats were used in these experiments, it would appear that the secondary response was suppressed to a slight extent in all the groups receiving anti-lymphocytic antibody (compare rats A with rats B). This suppression was observed irrespective of the treatment before primary stimulation. As has been observed earlier<sup>3</sup>, the inhibition of the secondary response is not so sensitive to anti-lymphocytic antibody as the primary phase. It is possible

that more effective suppression of the secondary response may be achieved by administration of larger amounts of these preparations, or by using stronger (more avid) antisera, such as the rabbit anti-rat lymphocyte material. Monaco *et al.*<sup>3</sup> have already indicated that the degree of inhibition of the secondary response is proportional to the amount of anti-lymphocytic antibody administered. Prolonged pretreatment of this kind might also have prevented the marked primary response observed in the Wistar strain rats.

antibodies (quantitatively and qualitatively), and this may in part explain the reduced humoral antibody production after secondary stimulation.

These results also suggest a number of points of possible practical importance in the production of anti-lymphocytic antibody and its use in transplantation. The preparation of purified IgG possessing anti-lymphocytic activity may in some cases obviate the costly process of absorbing the preparation to remove erythrocyte agglutinins. Furthermore, the use of such preparations makes

Table 3. EFFECT OF ANTI-LYMPHOCYTIC ANTIBODY ON THE SECONDARY RESPONSE OF HOODED RATS TO SHEEP ERYTHROCYTES

Treatment before		Lymphocyte count		Reciprocal agglutination titre												Days after primary challenge
Primary	Secondary	3 Days before secondary	Before injection of antigen	<2	2	4	8	16	32	64	128	256	512	1,024	2,048	
A Horse antibody IgG	Horse antibody IgG	3,250 (100)	2,760 (85)	—	—	—	1	1	1	1	1	—	—	—	—	14

B No pretreatment	Normal rabbit serum	—	—	—	1	1	—	—	—	—	1	—	—	—	—	14
				—	—	1	1	—	—	—	—	1	—	—	—	19

All the rats received daily intraperitoneal injections of 2 ml. of whole serum (antibody or normal) or IgG globulin (antibody or normal) on the 3 days immediately before primary or secondary stimulation with  $1 \times 10^6$  sheep erythrocytes. The humoral antibody response was assessed 5 days following secondary stimulation.

These results do not, of course, reveal what mechanisms are responsible for the inhibition of antibody formation with anti-lymphocytic serum. Nevertheless, the observation that antibody IgG suppresses the formation of humoral antibody after primary antigenic stimulation without producing a significant lymphopenia merits further comment. It is possible that the preparation of antibody IgG, which we have found also produces prolonged skin homograft survival, preferentially inactivates a small proportion of cells with a pronounced capacity for producing antibody because of a particular responsiveness to antigenic stimulation. The possibility that there are two sets of immunologically competent cells with differential sensitivity to anti-lymphocytic serum has previously been put forward<sup>4</sup>. The surviving lymphocytes may have been present from the start or may have been produced as the result of lymphoid hyperplasia of a small number of cells. These cells may be intrinsically inactive or else rendered so by coating (blindfolding) with antibody. The failure of antibody fragments which bind *in vitro* to inhibit the primary immune response would, however, suggest that a "blindfolding" mechanism may not be involved, although this should be more clear when fluorescent antibody studies have been performed to determine whether these materials do indeed coat lymphocytes *in vivo*. Moreover, on the basis of the results obtained with the rabbit antiserum it is possible that F(ab')<sub>2</sub> and Fab' preparations from more avid antibody may be capable of inhibiting the primary immune response and experiments are at present being performed to test this hypothesis. As well as the possible effect of ALS on the recognition of antigen, this material might also influence the ability of immunologically competent cells to produce

unnecessary the administration of large amounts of non-antibody protein, part of which possesses anti-enzyme activity which could disturb normal metabolic processes and perhaps influence subsequent graft survival. The few results so far available with rabbit antisera indicate, at least for rats, that this material may be preferable to horse preparations. The erythrocyte agglutinins were readily absorbed from the rabbit antisera and the resultant extremely cytotoxic preparations caused almost complete suppression of humoral antibody formation after primary stimulation. Finally, the anti-lymphocytic activity of the rabbit antisera was located in the 7S region and therefore is readily amenable to isolation.

We thank Professor M. F. A. Woodruff for his advice and encouragement, Mr. J. Watt of the Royal Dick Veterinary School, Edinburgh, for injecting and bleeding the horse, and V. Jubb, E. Nelson and E. McLeod for valuable technical assistance.

## Specific Proteases of the Rat Mast Cell

Labelled inhibitors have been used to study the activity and properties of a chymotrypsin-like enzyme in rat mast cells. In conjunction with light microscopy (this article) and electron microscopy (second article, page 1202), the method yields estimates of the numbers and locations of the enzyme molecules.

AMONG a number of active agents bound in the mast cell are enzymes with both specific protease and esterase actions, which are believed to be important in the activities of these cells. An abundant esterase activity was first detected histochemically<sup>1</sup>; Benditt and Arase<sup>2,3</sup> made extracts showing this enzyme activity and reported that it is inhibited by di-isopropylfluorophosphate (DFP) and hydrolyses esters of *N*-acetylated L-tryptophan, L-tyrosine and L-phenylalanine at relative rates similar to those of bovine pancreatic chymotrypsin. Further evidence for the similarity of the enzyme(s) in rat mast cell extracts to bovine chymotrypsin was reported by Lagunoff and Benditt<sup>4</sup>, based on parallel activities on a series of anilide substrates. The enzyme activity is located in the mast cell granules<sup>5</sup>, and it was shown also to possess endoprotease activity similar to that of chymotrypsin<sup>6</sup>. There have been reports of the presence of another enzyme similar in specificity to bovine trypsin, in the mast cells of the dog, in cat mastocytoma and in human mast cells<sup>6-9</sup>; trypsin-like activity is not, however, detectable in rat mast cells<sup>5</sup>.

This chymotrypsin-like enzyme (or enzymes) stored in the mast cell granules is of great interest. First, knowledge of the distribution and the fate of this enzyme would throw light on a degradative mechanism of mast cells, probably operating in some inflammatory<sup>10</sup>, immunological<sup>11</sup> and other<sup>12</sup> processes. Second, the apparent similarity of specificity to a pancreatic extra-cellular digestive enzyme raises biochemically significant questions. Is it similar in molecular weight, structure, active centre design and mechanism to bovine chymotrypsin, where these features are well known? Can such evidence be related to a common origin of these two enzymes, or has a similar function evolved independently? Is self-digestion prevented in the mast cells by the existence of a zymogen form, similar to chymotrypsinogen? If so, what controls activation? Such parallels, if established in diverse structures, would give considerable enzyme information.

Investigations of the purification of this enzyme are in progress (Kawiak and Barnard, unpublished), but the disruptive isolation necessary inevitably poses some problems about the initial state and properties of the component purified. We have found that much information can be gained by reaction of the protease *in situ* within the granules; such work, reported here, is also preferred for examining the cellular aspects of this enzyme.

The use of the labelled inhibitor technique in cytochemistry<sup>13,14</sup> has made possible new methods for quantitative investigation of some enzymes *in situ*<sup>15-18</sup> and this method was used as the basic tool in the present investigations. The organophosphate-sensitive esterases present were measured by the use of isotopically labelled (tritium or phosphorus-32) DFP, which is known<sup>19</sup> to phosphorylate irreversibly the serine residue at the active centres of these enzymes. The autoradiographic procedure<sup>15-18</sup> was applied to determine the amount of DFP taken up by the individual cells, and this reaction was followed in a variety of conditions to determine some properties of the reactive enzymes.

The basic procedure was as follows. Cell suspensions rich in mast cells were collected with saline (0.17 molar)

from the peritoneal cavities of male Sprague-Dawley rats (weighing 200–300 g). The cells were fixed in suspension in 4 per cent formaldehyde solution (buffered with 0.04 molar phosphate, pH 7.4, in 0.25 molar sucrose) for 2 h at 0° C, smeared and immediately washed. Tritiated DFP and phosphorus-32 DFP were each diluted with unlabelled DFP to a final specific activity of 100–200 mc./mmole and 2.1–4.0 mc./mmole respectively. In all cases this labelled

Fig. 1. *A*, Autoradiograph of a mast cell labelled with tritiated DFP (<sup>3</sup>H-DFP) (100 mc./mmole; 24 h emulsion exposure). (Oil immersion,  $\times 750$ .) *B*, A mast cell labelled with phosphorus-32 with  $\beta$  tracks (only two are in focus). (Oil,  $\times 750$ .)

DFP was applied to the smears at  $10^{-4}$  molar in 0.04 molar phosphate buffer, pH 7.4, at room temperature; at the end of all procedures the smears were washed in the buffer, and treated with unlabelled DFP ( $10^{-3}$  molar) for 30 min to remove unincorporated label. After all treatments the smears were post-fixed in ethylene-glycol monoethyl ether overnight at  $0^{\circ}\text{C}$ , which improves preservation of mast cells and completes washing. Autoradiographs were made either with 'AR-10' (Kodak) stripping film (for tritium)<sup>16</sup> or with 'G-5' (Ilford) liquid emulsion<sup>20</sup> ( $60\mu$ ) for phosphorus-32. The labelled material in the mast cells is so abundant that in the tritium autoradiographs (Fig. 1A) the emulsion exposure period was only 24–48 h. The mean of the grain densities over forty cells (after background subtraction) for each slide was used in each result presented.

Alternatively, when phosphorus-32 DFP and thick 'G-5' emulsion was used, the  $\beta$  particle tracks (Fig. 1B) were counted as described in detail for other cases<sup>18,21</sup>; this yields the number of disintegrations/cell/h of exposure, which, with the known specific activity, gives the absolute number of DFP-reactive sites in a cell.

**The reaction of mast cell enzymes with DFP.** This was measured autoradiographically in cells treated with tritiated DFP or phosphorus-32 DFP for various reaction periods from 2–128 min (Fig. 2). During about the first 30 min, the rate of DFP uptake (at  $10^{-4}$  molar) is fast, followed by a slow increase still observable at 128 min. The two slopes seen presumably indicate two different reaction rates with DFP, the first being caused by the reactivity of active centres of the enzymes with a high affinity for DFP, while the other indicates a slow reaction, which it is known could occur at less sensitive esterases<sup>22</sup> or certain other protein sites<sup>23,24</sup>. With tritium, because of the high self-absorption, only proteins in the superficial layers of the cytoplasm are revealed as reactive sites: the similarity in shape (Fig. 2) of this curve with that for total DFP uptake throughout the cell (phosphorus-32) confirms that the penetration of DFP through the cell is not limiting, so that the initial slopes of the curves represent the real rates of DFP reaction with the enzymes.

The mean number of DFP-reactive enzyme sites in a mast cell, that undergo the initial fast reaction, calculated from the track counts (Fig. 2), is  $6 \times 10^8$  (standard error  $0.3 \times 10^8$ ) for these cells, the mean diameter of which was  $16.1\mu$  (standard error  $3.2\mu$ ). To demonstrate the irreversibility of this DFP binding, cells were pre-treated with unlabelled DFP ( $10^{-3}$  molar for 30 min) and after washing were allowed to react with tritiated DFP. Final washes were as in the standard procedure. The very slow rate of tritiated DFP uptake (Fig. 2, lowest curve) then observed confirms the very slight reaction at less reactive sites, these not being fully blocked by only 30 min pre-

Fig. 2. Dependence of DFP reaction on incubation time (in the standard conditions). Upper line, grain counts over cells reacted with tritiated DFP; middle line, molecules of phosphorus-32 DFP reacting in each cell, derived from track counts; lower line, grain counts over cells pre-treated with DFP ( $10^{-3}$  molar for 30 min) and then reacted with tritiated DFP.

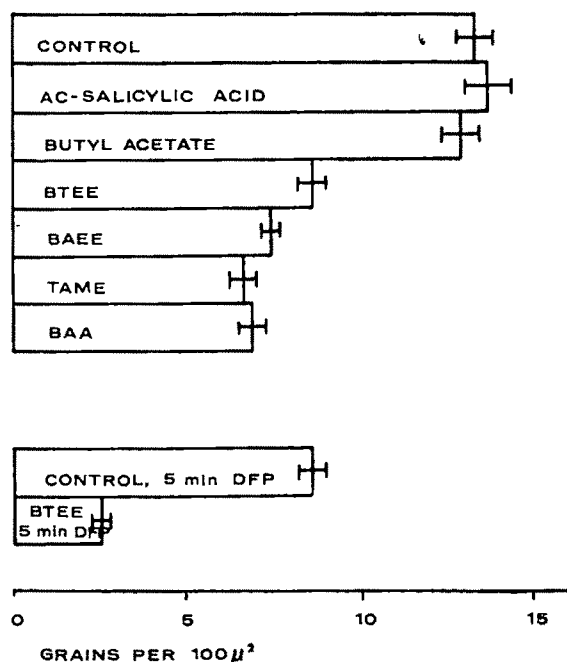

Fig. 3. Grain densities ( $\pm$  standard error) over mast cells after tritiated DFP reaction (upper block) for 16 min in the presence of: no substrate; acetylsalicylic acid; butyl acetate; benzoyltyrosine ethyl ester; benzoylarginine ethyl ester; tosylarginine methyl ester; benzoylarginine amide. All were  $5 \times 10^{-4}$  molar. The lower block shows a similar experiment, using BTEE only, in which the reaction time was 5 min only.

treatment with DFP. The adequacy of the standard washing is also confirmed by these observations.

To estimate the effect of formalin fixation, cells were reacted with tritiated DFP in suspension, either after the standard formalin fixation, or unfixed. The fixed cells showed 15 per cent greater ( $P < 0.01$ ) uptake of tritiated DFP. Thus, the fixation (and smearing) do not inhibit the reaction. The elevation might be caused by removal of an inhibitor, serotonin (see below), in fixation.

To examine the specificity and affinity of the DFP-sensitive enzymes, substrates were included in the tritiated DFP reaction bath. The competition of each substrate with DFP for the enzyme active centres was measured by the rate of inhibition of tritiated DFP uptake in its presence. Before labelling, the smears were equilibrated with the appropriate substrate for 30 min, then tritiated DFP ( $10^{-4}$  molar) was applied for 16 min in solution.

The following compounds were tested, thus, for protection, at  $5 \times 10^{-4}$  molar concentration: *n*-butyl acetate (Fisher), acetylsalicylic acid (Matheson), benzoyl-L-tyrosine ethyl ester (BTEE) (Mann), benzoyl-L-arginine ethyl ester (BAEE) (Mann), *p*-tosyl-L-arginine methyl ester (TAME) (Mann) and benzoyl-L-arginine amide (BAA) (Mann).

The first two substrates were tested to reveal the so-called "non-specific esterases" with very wide specificity for esters<sup>27</sup>, either aliphatic or aromatic or both. BTEE is known to be a highly specific substrate for chymotrypsin<sup>28</sup>. BAEE and TAME are the substrates preferred by trypsin and trypsin-like enzymes<sup>28</sup>. BAA is an amide substrate of trypsin-like enzymes. The results (Fig. 3) show that the two non-specific substrates have no significant effect on the mast cell enzymatic reaction with DFP. The chymotrypsin substrate, BTEE, inhibits uptake of tritiated DFP in these conditions by about 35 per cent, while the three trypsin substrates exert even stronger protection, each about 40 per cent. The substrates are reversibly bound, and so

Fig. 4. Grain densities ( $\pm$  standard error) after tritiated DFP reaction (16 min) alone, or after treatment (60 min) with  $3.4 \times 10^{-4}$  molar TPCK or with  $3.4 \times 10^{-4}$  molar TLCK.

protection from the irreversible inhibitor DFP cannot be absolute, but must decline with time at a rate related to the reaction velocity of DFP with enzyme; kinetic investigations, which yield affinity constants *in situ* for substrates, will be presented elsewhere.

We can note here that when a series of concentrations of BTEE is used ( $1 \times 10^{-4}$  molar to  $1 \times 10^{-3}$  molar) and inhibitions are measured at short times (as little as 2 min) of the tritiated DFP reaction, the extent of protection by BTEE can reach a maximum of 85 per cent. Thus, most of the labelled enzymes have a specificity somewhat similar to that of chymotrypsin. The benzoyl group is not essential, because acetyl-L-tyrosine ethyl ester (Mann) used similarly gave about half the protection that BTEE gave. L-Leucinamide gave no protection.

Reaction with specific irreversible inhibitors was examined. A reagent that is extremely specific for alkylation of the active centre of pancreatic chymotrypsin, L-1-tosylamido-phenylethylchloromethyl ketone (TPCK) was designed by Schoellman and Shaw<sup>25</sup>. After this alkylation, chymotrypsin can no longer react with DFP<sup>26</sup>. L-1-Tosylamido-2-leucylchloromethyl ketone (TLCK) reacts similarly with trypsin<sup>26</sup>. In view of the resemblances reviewed above, it is of interest to apply TPCK and TLCK to the mast cell enzymes as probes for the chymotrypsin and trypsin types of active centre.

The cells were treated with TPCK or TLCK ( $3.4 \times 10^{-5}$  molar) in 3 per cent methanol in the pH 7.4 phosphate buffer for 30 and 60 min. (Control cells were exposed to the same medium with the inhibitor absent.) After buffer washes, the standard tritiated DFP procedure was applied. In all cases (Fig. 4) the DFP uptake was normal. The difference (8 per cent) between the control and TPCK-pretreated cells is not statistically significant. Checks made with bovine pancreatic chymotrypsin and trypsin showed full inhibition of these by the TPCK and TLCK media (respectively) used.

The lack of inhibition by TPCK appears to be the first significant difference detected between the chymotrypsin-like enzyme of the rat mast cells and pancreatic chymotrypsin itself. In confirmation, recent experiments in this laboratory (Dr. J. Kawiak, to be published) show that the enzyme, isolated from rat mast cells, that has high activity on the chymotrypsin substrate BTEE, is scarcely inhibited in solution by TPCK (but see note added in proof). The lack of effect of TLCK on the uptake of DFP shows that an enzyme with an active centre similar to that of pancreatic trypsin is also absent in these cells.

Serotonin (5-hydroxytryptamine) and histamine are known to be stored in living mast cells. The effect (reported above) of fixation on the DFP reactivities, whereby fixed and washed cells react faster than unfixed, living cells, together with reports of the inhibitory effects of tryptamine on pancreatic chymotrypsin activity<sup>29</sup> and of serotonin on the autocatalytic activation of trypsinogen<sup>30</sup>, suggested a possible inhibitory function of serotonin on the mast cell proteases. Testing this, the fixed cells were treated for 30 min with serotonin at  $5 \times 10^{-4}$  molar or  $10^{-4}$  molar, in the pH 7.4 buffer (room temperature), and next underwent treatment with tritiated DFP ( $10^{-4}$  molar)

in the presence of serotonin ( $5 \times 10^{-4}$  molar) for 2–64 min (Fig. 5). A marked lowering of tritiated DFP uptake in the presence of serotonin is seen, indicating its inhibition of the enzymes, but a further, interesting phenomenon is observed: DFP reaction decreased progressively (by about 30 per cent) in the cells during the last 32 min of incubation. The phosphorylation is irreversible, and so this is explained as a result of an extraction by serotonin of the labelled enzymes from the cells. (In these serotonin-treated, fixed cells, no degranulation was apparent.)

This interpretation is supported by an unusual spread of the radioactivity into the emulsion from the serotonin-treated mast cells, where a halo 20–40  $\mu$  wide, of dense background labelling, was observed. For further confirmation (Fig. 6, lower block), cells were treated with serotonin ( $5 \times 10^{-4}$  molar) alone (a) for 10 and 20 min after labelling, and (b) for 60 min before labelling (with tritiated DFP alone). In both (a) and (b), a significant decrease of the incorporated label is seen, increasing with the duration of serotonin treatment. Thus, serotonin at low concentrations extracts these mast cell enzymes, both in their original and their phosphorylated forms.

The inhibitory effect of serotonin, independent of extraction, was also measured. Cells were exposed to serotonin ( $5 \times 10^{-4}$  molar) for 5 min and then to tritiated DFP and serotonin together; control cells had the serotonin exposure for 10 min and were then reacted with tritiated DFP (alone) for 5 min. Thus, both groups of cells were exposed to serotonin for 10 min, so that the extractive effects should be identical; from a difference in labelling the binding of serotonin at the enzyme active centres could be separately evaluated. It was seen (Fig. 6, upper block) that serotonin is strongly inhibitory. Further investigations of effects of serotonin on mast cell proteases, including actions on unfixed cells and inhibition of the activity of isolated proteases, will be reported in full elsewhere. Histamine, as another bio-active amine concentrated in mast cells, was tested similarly, but it has failed to exhibit any powers of inhibition or extraction of the enzymes examined here (see Fig. 7).

In conclusion, the reaction of labelled DFP with the proteases of mast cells opens up new analytical approaches to their investigation. Among others, the following points can be established. (1) The absolute number of the organophosphate-reactive protease or esterase molecules in individual mast cells has been determined. Problems of fractionations are avoided. Only mast cells are labelled at this low exposure, and so other cells present do not interfere. It should be noted that this number in each cell is so large that, even if these enzymes are all of molecular weight (in each active centre) of only 20,000, they would constitute at least 10 per cent of the known<sup>31</sup> total dry mass of the rat mast cell (which already includes much heparin, about 30 per cent by weight of the gran-

Fig. 5. Rates of tritiated DFP uptake in mast cells, measured by grain density ( $\pm$  standard error), in the presence of serotonin (5-HT) at two concentrations, or in its absence (control).

ules<sup>32</sup>). This enormous enzyme concentration suggests storage for a degradative role in mast cell function. It also indicates that the main enzyme(s) here must be of the order of 20,000 or less in molecular weight.

(2) At least 85 per cent of these enzyme molecules resemble chymotrypsin in affinity for  $\beta$ -aryl structures. The inhibition by BAEE and TAME can also be attributed to the same cause, involving their aromatic substituent; no hydrolysis of these substrates can be found in extracts of these rat cells (Dr. J. Kawiak, unpublished), confirming other reports<sup>32</sup>. The serotonin affinity found also fits a chymotrypsin-like binding site.

(3) This mast cell enzyme has an active centre, therefore, with a binding site similar to that of chymotrypsin and with the activated serine (presumed from the DFP reactivity), but without the active histidine (responsible<sup>28</sup> for TPCK reactivity) (but see note added in proof).

(4) The active centres are fully available in the intact cell, so that a zymogen or precursor protein does not occur. Serotonin (but not histamine) has a high affinity for the active centre of this enzyme; this is indicative, although not conclusive, of a role of serotonin in inhibiting protease activity in the intact mast cell. The slow extraction by serotonin seen later is not inconsistent with this role: the concentration of serotonin may act as a control, restraining protease activity at small concentrations and releasing it in physiological processes when the free serotonin concentration rises.

(5) The location of this enzymatic activity in the mast cell granules<sup>32</sup> can be proved in intact cells by electron microscope autoradiography after tritiated DFP reaction (see succeeding communication); this can also provide useful extensions of these investigations.

(6) The reaction with isotopic DFP can be used to label mast cells for *in vivo* work, to follow the cells and their granules and the fate of the enzyme in functional situations<sup>33</sup>.

This work was supported by grants from the U.S. Public Health Service and from the Damon Runyon Memorial Fund. We thank Miss Eliza Ferby for technical assistance.

*Note added in proof.* These experiments have now been extended (Kawiak and Barnard, to be published). The protease has been isolated in pure form from rat peritoneal

mast cell granules. It has a high activity on BTEE and on casein, and is rapidly inhibited by DFP. It is, however, irreversibly inhibited by TPCK, but at a very slow rate: the half-time for activity loss with  $4 \times 10^{-4}$  M TPCK (a very large molar excess over the enzyme) at pH 7.8, 25°, is 4 h. This is very much slower than the inactivation rate with pancreatic chymotrypsin. Thus our inability to react the protease *in situ* in our conditions is to be expected, from this low reactivity. The difference involved between the mast-cell chymotrypsin-like enzyme and pancreatic chymotrypsin is therefore quantitative rather than qualitative. The active centres must be similar, but nevertheless must differ in some important feature determining this rate.

### Intracellular Localization of Specific Proteases in Rat Mast Cells

THE possibility of applying radioactive organophosphate inhibitors of high specific activity to localize sites of esterase activity by autoradiography has permitted estimates, in several specific cases, of the number of enzyme active centres present in individual intra-cellular sites<sup>1,2</sup>. For the rat peritoneal mast cell, it has been found (see preceding article) that the absolute number of organophosphate-reactive enzyme molecules with protease (and esterase) activity in individual mast cells can be determined thus, without the problems incurred in fractionating cell components.

While previous investigations by fractionation methods indicated that this enzyme activity is located (at least for the most part) in the specific granules of the mast cell<sup>3</sup>, an *in situ* confirmation of this is highly desirable. Further, an *in situ* analysis should provide a complement to the isolation investigations, for the latter cannot determine whether distribution in a granule is homogeneous or heterogeneous, nor whether the enzyme component occurs in all of the granule population of a cell or only in one fraction of it. Other functional components of the rat mast cell, such as heparin, serotonin and histamine, are also thought to be bound in the granules<sup>4,5</sup>, and it will be essential for an understanding of the activities of mast cells to know whether all occur together with the protease in all the specific granules, or whether there is segregation in different granule types, and, if so, which components are structurally associated. The autoradiographic method, taken to the moderately high resolution attainable in electron microscope autoradiography, should be competent to examine such questions in the case of the mast cell granules.

The reactive enzyme fraction in the mast cell is so abundant that, when using tritiated di-isopropylfluorophosphate (tritiated DFP) at a specific activity of 1 c./mmole (well below the maximum available), adequate labelling for quantitative investigations is obtained over each mast cell in electron microscope autoradiographs (using ultra-thin sections and emulsion layers) after only 6 days exposure to emulsion. We report here such results on rat peritoneal mast cells after 6–50 days exposure, employing methods giving a resolution sufficient to resolve labelling at the level of individual granules. The same approach has concurrently been used on the mast cells of mouse skeletal muscle<sup>6</sup>.

Mast cells were obtained as described in the preceding communication, and fixed in suspension in buffered glutaraldehyde (3 per cent, in 0.04 molar sodium phosphate/0.25 molar sucrose, pH 7.4) for 2 h at 0° C. Using centrifugations, they were, in turn, washed in the buffered sucrose (20 min), treated in suspension with 10<sup>-4</sup> molar tritiated DFP (1.0 c./mmole, in the buffered sucrose, 20 min at room temperature), washed in the buffered sucrose (20 min) and treated with unlabelled 10<sup>-3</sup> molar DFP (in buffered sucrose, 20 min) to remove unincorporated label. The cells were then transferred to ethylene-glycol monoethyl ether for 24–48 h at 0° C. Dehydration was in graded concentrations of ethanol after a treatment in water (1 h) with 1 per cent osmium tetroxide (pH 7.4). Cells were embedded in 'Araldite', sectioned and coated with Ilford 'L<sub>4</sub>' emulsion using the membrane technique<sup>6</sup> (developed in 'D163' or 'Mierodol X' or with Kodak 'NTE' emulsion<sup>7</sup> (developed in 'Dektol').

Both granulocytes and agranulocytes, as well as other cells, also occurred in the samples, but with minor ex-

ceptions only mast cells were labelled. Cytological preservation was very good. Silver grains occurred in a well defined distribution over each mast cell in all autoradiographs after 6 to 50 days exposure. By far the heaviest incorporation was into the specific granules (Fig. 1; Table 1). Two, or possibly three, kinds of granule were recognized morphologically, but the relation of the grains to each type showed no discernible differences. Examination at heavier grain densities (which was undesirable for the initial analysis) will be needed (and feasible) to determine whether smaller quantitative differences exist in this component between types of granule. Most nuclei had only 1–3 grains, which were over the electron-dense

Fig. 1. Electron microscope autoradiograph of a section through a labelled mast cell, showing silver grains associated with the granules. A, 'L<sub>4</sub>' emulsion ( $\times 7,440$ ). B, Another section in higher resolution using 'NTE' emulsion (after 50 days exposure;  $\times c. 12,900$ ).

chromatin, but occasional cells had rather more grains in this region (one such cell was included in the 6 day counts in Table 1).

Table 1. GRAIN DISTRIBUTION OVER PERITONEAL MAST CELLS REACTED WITH TRITIATED DFP

Experiment	Exposure	Total grains	Specific granules	Non-granule cytoplasm	Nucleus
1	6 days	123	100	9	14
2	44 days	116	111	2	3

Counts were made over a number of sections, to the grain totals shown, and these were recorded as occurring over one of the three cell compartments listed. The relative areas of the components were also measured by the point grid method<sup>10</sup> over sections from seven cells: the non-granule cytoplasm occupies 16 per cent by area, but has only 5 per cent (mean) of the total cytoplasmic label. This small cytoplasmic fraction of label outside the granules is taken to be due to spread of radiation from the granules, which must occur in these conditions if only they are labelled; the lower resolution ('L<sub>4</sub>') conditions were used here.

In the conditions we have used, a resolution of at least 0.2 $\mu$  for 'L<sub>4</sub>' emulsion and 0.1 $\mu$  for 'NTE' is predicted<sup>6-8</sup>. In Fig. 2 is plotted the distribution of the developed grains in 'NTE' emulsion over equal areas of granule material, for sections of granules having a radius of 0.4 $\mu$  to 0.65 $\mu$ . Each grain was recorded as a function of its distance ( $d$ ) from the limiting membrane of the associated granule of measured radius ( $r$ ). Limits for  $d/r$  representing a division of the granule into three equal concentric areas were calculated, and each grain was assigned to one or other of these compartments. It was seen that all of a granule is labelled and there is no preferential localization of label in the peripheral or central areas.

Serious errors might be risked if the osmium tetroxide post-fixation could remove some di-isopropylphosphoryl groups, or produce extractions<sup>9</sup> of protein. That this does not occur was established by an experiment using liquid scintillation counting of total extracts of treated cells (Table 2).

We consider that the labelling reveals the sites of the mast cell chymotrypsin-like enzyme(s), on the evidence presented in the previous article. Thus, we conclude that this enzyme is indeed localized in the granules.

That fraction of the label which is definitely not in the granules is in the chromatin of the nuclei. This is a small and variable fraction: some cells had no nuclear labelling. Two possible explanations can be offered. First, the mast cell protease is a strongly basic protein fraction when isolated<sup>3</sup>, and so it can combine with heparin, but also with DNA in mast cell homogenates (Dr. J. Kawiak, unpublished data). It may combine in the mast cell

Fig. 2. Histogram showing the distribution of developed grains in 'NTE' emulsion over equal areas of granule material in and around sections of individual granules of radius ( $r$ ) 0.4 to 0.65 $\mu$ . The numbers of counted grains that lie within one or other of three equal concentric areas are plotted. The limits of these areas are defined by the values of  $d/r$  shown on the horizontal axis, where  $d$  is the distance from the grain to the nearest granule boundary. Positive values denote distances within a granule.

nucleus as histones do, either naturally or from a few disrupted granules in those cells (although no discernible damage was associated with nuclear labelling). Second, the chromatin-bound enzyme might be newly synthesized on polynucleotide synthetic centres in these nuclei. This compels further investigation.

Table 2. ABSENCE OF ARTEFACTAL DECREASE OF LABELLING BY OSMIUM TETROXIDE ACTION

Mean counts per min from each sample		Control cells	
Osmium tetroxide-treated cells			
a	3,957 c.p.m.	d	4,189 c.p.m.
b	3,857 c.p.m.	e	3,853 c.p.m.
c	4,268 c.p.m.	f	4,186 c.p.m.
Mean	4,024 c.p.m.	Mean	4,076 c.p.m.

Mast cells were treated by the procedure used for the electron microscope specimens, up to the stage of the unlabelled washing with DFP (but using 5 per cent (w/v) formaldehyde in place of the glutaraldehyde, and with the tritiated DFP specific activity at 120 mc./mmole). They were then efficiently suspended and equally divided in six portions, in 0.04 molar sodium phosphate, pH 7.4, buffer (1.2 ml. total). Samples a, b and c were each treated with osmium tetroxide (2 per cent, in the buffer, 1 h at 0° C), while d, e and f remained in the buffer alone. After buffer washings, each sample was extracted with 0.5 ml. of NCS solubilizer (Nuclear Chicago, Inc.), 16 h. with rapid shaking for 4 h at room temperature, taking all the material into solution. Toluene (15 ml.) containing scintillation materials was added to each, giving clear solutions, which were counted in a Packard 3224 liquid scintillation counter at 7° C. The efficiency was identical in all tubes (and background was 34 c.p.m.); the mean counts, therefore, represent the bound isotope in equal quantities of cells.

It was seen in the light microscope autoradiography described in the previous article that all mast cells in the population contain this enzyme component, and that they are without very marked variations in their content of it. We see here that it is generally distributed among the granules in each cell. We can note that the penetration of DFP to all the sites can be assumed, because the absolute number of reacted sites<sup>2</sup> is large enough to show that all of this enzymatic protein does react. The reaction is also not reduced by previous fixation (see preceding article).

A further analysis of mast cells reacted with tritiated DFP and a detailed series of electron micrographs will be published elsewhere. More extensive labelling and higher resolution are technically feasible. High resolution studies have been pursued on mouse muscle mast cells<sup>4</sup>. It also seems to be possible to extend the electron microscope autoradiographic approach to some other functional components of the mast cell, by suitable incorporations of label (biosynthetically); combination with the protease investigations should then achieve an analysis of the associations of these components in individual granules.

This work was supported by grants from the U.S. Public Health Service and from the Damon Runyon Memorial Fund. We thank Dr. Miriam Salpeter (Cornell University) for her helpful discussion and interest.

## Seasonal Variation in the Concentration of Caesium-137 in Grass and Alfalfa

by

S. CSUPKA

M. PETRÁŠOVÁ

J. CARACH

Regional Station of Hygiene and Epidemiology,  
Department of Radiation Hygiene,  
Bratislava, Czechoslovakia

Analyses of the content of caesium-137 and other radionuclides in grass and alfalfa in Western Slovakia during 1962–65 indicate that such measurements provide a means of determining the rate of radioactive fall-out from nuclear weapon tests, provided certain climatic factors are taken into consideration.

THE accumulation of radioactive caesium-137 as a by-product of nuclear fission is of considerable importance because of its long half-life. Radiocaesium enters plants either by absorption from the soil by the root system or by assimilation of free deposits on various parts of the plant.

The penetration of caesium-137 into plants is frequently studied in connexion with the properties of soils. Essentially soils consist of a polydispersed system of organic and inorganic substances. Clayey mineral colloids and humous organic colloids are interbonded in the soil to form a complex organo-mineral sorbent which is capable of "fixing" such plant nutrients as phosphates, sulphates and water in the soil. The soil solution is very dilute and only a small proportion of the plant nutrients is actually present in it because most of them are bonded to the mineral particles and especially to the humous sorbent complex. The concentration in the soil solution also depends on the sorptive forces between the ions and the soil particles, as well as on the number and nature of the cations and anions present.

Compared with strontium, caesium is firmly bonded with the sorptive soil complex because it has a greater ionic radius and a smaller hydration envelope than strontium. This is one reason why caesium is not washed into the soil solution as easily as strontium and, consequently, is relatively less diffused in the plant. The removal of radiocaesium from the soil by plants depends on the mutual relations of various anions and cations present in the soil. Shone<sup>1</sup> extracted caesium-137 from the soil-type "greensands" in the presence of various electrolytes, and found that calcium chloride is most efficient in reducing the removal of caesium from the soil. A high concentration of calcium makes it more difficult for caesium to be removed from the soil by plants<sup>2</sup>, while a high concentration of sodium and potassium makes it easier.

It is known that up to 70–80 per cent of the caesium-137 from fall-out is fixed and concentrated in the upper organic layer of the soil and remains there in an "unavailable" form<sup>3</sup>. According to Squire<sup>4</sup>, absorption of caesium-137 from the soil by grass represents between a twentieth and a quarter of the strontium-90 taken up—the proportions being determined by the nature of the soil, the pH and the calcium content of the soil.

The relative concentration factor for caesium-137 between plants and the soil is in the region of 0.01–1 (ref. 5), that is, the concentration of caesium in plants is lower than that in the soil provided only the uptake by the root system is taken into account. It is evident from numerous

experiments<sup>6–9</sup> that the uptake of radionuclides from a contaminated soil by the root system is slight compared with the direct contamination in other parts of plants. Wijk and Braams<sup>10</sup>, who followed the removal of caesium-137 by grass over a period of several months, found that in artificially contaminated soil grass absorbed only some tenths of a per cent of the radiocaesium. By means of autoradiographs, Middleton<sup>11,12</sup> showed that leaves are subject to direct contamination by caesium-137 when it is sprayed on to them.

It thus follows that so far as the deposition of radionuclides on plants and foliar absorption are concerned, the most important factor is the direct contamination of the aerial part of the plant or the rate of radioactive fall-out. This supposition is supported by the findings of

Fig. 1. Comparison of the activity of caesium-137 in fall-out and in grass during 1962–63. Top curves: —, fall-out; ----, rain. Bottom curves: —, mean values; ----, maximum and minimum values.

Fig. 2. Comparison of the activity of caesium-137 and the mean ratio of caesium-137 : strontium-90 in alfalfa, in 1963. Top curves: —, ratio  $^{137}\text{Cs}/^{90}\text{Sr}$ ; ---, rain. Bottom curves: —, mean values; ---, maximum and minimum values.

Evans and Dekker<sup>13</sup>, who traced the activity of various agricultural products and found that uncovered alfalfa shows 80 per cent more activity than covered alfalfa.

The radiocaesium content in vegetation varies throughout the whole vegetative period. In order to determine the content of caesium-137 in grass and alfalfa during the period of growth and its accumulation during the vegetative period, samples of these plants were analysed several times a year from 1962 onwards from the regions of Bratislava, Trnava, Jaslovské Bohunice and Piešťany in Western Slovakia. Sampling was on a monthly basis for 2 years and thereafter only twice a year. Caesium-137, in the form of caesium tungsto-silicate<sup>14,15</sup>, was obtained from 100 g of each sample, which had been dried at 105° C and burnt at 450° C, and the  $\beta$ -activity measured.

Fig. 1 shows values for the average activity of caesium-137 obtained from grass samples taken over the period 1962–63 and Fig. 2 gives those obtained from alfalfa. We have also plotted the maximum and the minimum values obtained over separate months at various areas. The graph shows that samples taken on a more frequent basis do not yield results revealing any further marked changes in the content of caesium-137 when expressed per unit of dried matter. There would seem to be a definite relationship, however, between the fall-out, the rainfall and the caesium-137 activity in grass and alfalfa. The activity of caesium-137 in fall-out increases with increased precipitation; however, it drops in grass and alfalfa probably because deposits of caesium-137 on the leaves and flowers are washed into the soil by rain. There are, of course, other climatic factors which influence the level of activity of caesium-137 in the vegetation, the most important of which is the wind. As a result of the action of rain and wind, the soil and the vegetation of some regions may become enriched in radioactive substances,

although in other regions they may become impoverished. Besides the climatic factors, the shape and size of the leaves play an important part in the relationship between plants and radioactive substances. Alfalfa, for example, has a leaf area of 85.6 m<sup>2</sup>/m<sup>2</sup> of soil, while maize has only 2.7 m<sup>2</sup>/m<sup>2</sup>.

The ratio of caesium-137 : strontium-90 provides evidence that the main part of activity of caesium-137, especially in the years after the nuclear bomb tests, comes from fall-out. In alfalfa this ratio is directly related to the fall-out and moves within the limits 1–2 (see Fig. 2).

We followed the activity of caesium-137 in grass and alfalfa obtained at the first and second mowings over a period of 4 years (Table 1). (The first mowing covers the period April–May and the second the period June–August.) The results given in Table 1 for precipitation and for the activity of the caesium-137 in the fall-out and in the vegetation represent cumulative values for the period of active vegetative growth. They show that the activity of radiocaesium in grass and alfalfa is higher in spring than in summer. This indicates the considerable influence which rain has because the fall-out is greater in spring than in the other seasons of the year and this has a direct influence on the intensity of the activity of caesium-137 in grass and alfalfa.

Table 1. COMPARISON OF THE ACTIVITY OF CAESIUM-137 IN GRASS AND ALFALFA DURING TWO MOWING PERIODS IN EACH OF THE YEARS 1962–65

Year	Mow- ing period	Rain- fall (mm)	Deposit $^{137}\text{Cs}$ (nc./m <sup>2</sup> )	K (g/kg)	Grass $^{137}\text{Cs}$ (pc./kg)	$^{137}\text{Cs}/\text{K}$ (pc./g)	K (g/kg)	Alfalfa $^{137}\text{Cs}$ (pc./kg)	$^{137}\text{Cs}/\text{K}$ (pc./g)
1962	(1)*	101	1.51	11.8	1,221.8	103.5	—	—	—
	(2)	94	2.79	6.0	1,000.8	166.8	—	—	—
1963	(1)	62	8.51	13.9	1,088.8	78.3	15.9	1,408.9	88.6
	(2)	218	11.42	21.4	1,225.3	57.2	16.2	1,810.2	111.7
1964	(1)	102	4.72	18.3	786.7	43.0	17.5	940.0	53.7
	(2)	152	5.20	13.5	586.2	43.4	—	—	—
1965	(1)	250	2.45	18.7	655.0	35.0	15.9	317.7	20.0
	(2)	282	2.52	15.1	430.2	28.5	—	—	—

\* (1) Measurements made during the period April–May; (2) measurements made during the period June–August.

There is no substantial difference between the activity in grass and that in alfalfa in any one vegetative season, except that, on average, it is 20 per cent higher in alfalfa than in grass. The potassium content in the plant is relatively constant and, because the activity of radiocaesium in the samples tested shows a tendency to decrease, the ratio caesium-137 : potassium also tends to decrease. A substantially lower content of potassium in grass in 1962 (6.0 g potassium/kg of dried matter) resulted from an early arrest of active vegetative growth due to intense heat and excessive drought in August.

Table 2 gives the annual average content of caesium-137 and strontium-90 in grass and alfalfa, computed for a 4 year period so that a comparison can be made with the amounts in the fall-out. Even the heavy rainfall of 1965 failed to increase the amounts of the two radionuclides in the fall-out. This suggests that to a great extent the radionuclides thrown out by the intensive tests with nuclear weapons during the period 1961–62 have been cleared from the stratosphere. In 1965 the content of caesium-137 in the fall-out dropped by 70 per cent and the content of strontium-90 by 80 per cent as compared with 1963 when the fall-out reached a maximum.

Table 2. CONTENT OF CAESIUM-137 AND STRONTIUM-90 IN GRASS AND ALFALFA IN WESTERN SLOVAKIA DURING 1962–65

Year	No. of samples Grass    Alfalfa	Mean annual rainfall (mm)	Annual cumulative deposit (nc./m <sup>2</sup> )		Caesium-137 (pc./kg)		Strontium-90 (pc./kg)		Mean ratio: $^{137}\text{Cs}/^{90}\text{Sr}$	
			$^{137}\text{Cs}$	$^{90}\text{Sr}$	Grass	Alfalfa	Grass	Alfalfa	Grass	Alfalfa
1962	16	—	583	8.78	12.66	959.0	860.2	—	1.1	—
1963	24	24	558	28.98	22.50	1,365.3	1,335.9	1,000.3	1.0	1.2
1964	7	6	555	15.46	16.86	686.4	869.2	911.1	0.8	1.5
1965	8	13	827	7.75	5.29	535.4	470.4	496.5	1.1	0.8
Mean ratio:										
1965/1962	—	—	1.4	0.9	0.4	0.5	0.6	—	—	—
1965/1963	—	—	1.5	0.3	0.2	0.4	0.5	—	—	—
1965/1964	—	—	1.5	0.5	0.3	0.8	0.5	1.0	—	—

The effects of less fall-out together with high precipitation could be detected in the lower proportion of these two radionuclides present in plants. Compared with 1963, the activity of caesium-137 in grass decreased by 60 per cent and in alfalfa by 70 per cent in 1965. For the same period, the drop in the activity of strontium-90 in grass was 60 per cent and in alfalfa 50 per cent and the ratio of caesium-137: strontium-90 ranged approximately from 1 to 1.5.

These results show that the variations in the content of caesium-137 in grass and alfalfa under natural conditions during the period 1962-65 depended mainly on the rate of radioactive fall-out in a given area. Cumulative deposition of caesium-137 in the soil of the region tested was not markedly manifested by an increased removal of caesium-137 by grass and alfalfa.

## Persistent Binding of Butter Yellow Metabolites to Rat Liver DNA

by  
G. P. WARWICK  
J. J. ROBERTS

Chester Beatty Research Institute,  
Institute of Cancer Research,  
Royal Cancer Hospital, London

Radioactive metabolites of butter yellow (<sup>3</sup>H-dimethylaminoazobenzene) have been found to bind covalently to the liver DNA of hooded rats. The specific concentration of radioactivity dropped to roughly a half its initial value in the first 7 days and then remained roughly constant for 3 months, which implies an absence of repair. This observation could explain chromosome aberration observed in regenerating liver after treatment with carcinogens and may play a part in the latent period in the carcinogenic process.

AFTER a single intraperitoneal injection (150 mg/kg) of dimethylaminoazobenzene (DAB) labelled with tritium in the primed ring, radioactive drug metabolites were bound covalently to the ribosomal RNA (rRNA), the cytoplasmic and nuclear proteins, and to the DNA of the liver<sup>1</sup>, spleen<sup>2</sup> and kidney<sup>2</sup> of male albino rats. The maximum level of binding to rRNA was 114  $\mu$ moles/g while for DNA it was 14  $\mu$ moles/g. The level of radioactivity associated with rRNA and with the proteins decreased with time, the rate of decay paralleling the rate of turnover of these macromolecules. By contrast, the level of radioactivity bound to DNA remained constant for 12 days<sup>1</sup>.

This work was continued to determine the half life of the radioactivity associated with DNA, and six groups of three male hooded rats weighing about 200 g (Chester Beatty stock) were kept for periods of up to 3 months after a single intraperitoneal injection of 150 mg/kg tritiated DAB (specific activity 1.2 c./mmole). They were maintained on a diet containing 10 per cent protein<sup>1</sup> and allowed just sufficient food to keep weight increases below 20 per cent over 3 months. The groups were killed at 2 days, 1 week, 3 weeks, 6 weeks, 2 months and 3 months. The proteins, rRNA and DNA were isolated from individual animals and purified as previously described<sup>1</sup>. The DNA was purified by treatment with RNase, removal of residual proteins with phenol, and removal of glycogen with methoxyethanol. The DNA was converted to the cetyl trimethylammonium bromide salt, washed well with water, and reconverted to the sodium salt. Finally the DNA was dissolved in a solution containing 2 per cent sodium acetate and 1.5 per cent sodium chloride (0.5 mg/ml.) and spun for 1 h at 20,000 r.p.m. The supernatant was treated with two volumes of 2-ethoxyethanol to precipitate the DNA. DNA prepared in this way contained less than 2 per cent residual protein. For assay of radioactivity the DNA was dissolved in water (1 mg/ml.), and degraded with DNase. Portions (0.1-0.5 ml.) were assayed using a

liquid scintillation spectrometer. The rRNA and the proteins were purified and assayed as previously described<sup>1</sup>. The results showed good reproducibility from animal to animal within each group, the maximum variation being about  $\pm 20$  per cent. Results were expressed as an average for each group.

Radioactivity associated with liver rRNA and with the cytoplasmic proteins is shown in Fig. 1. The half-life of each was between 3 and 5 days and the rate of loss of radioactivity paralleled the rate of turnover of these macromolecules<sup>1</sup>. The levels of binding were similar to

Fig. 1. Binding of radioactive metabolites from tritiated dimethylaminoazobenzene to hooded rat liver DNA, rRNA and cytoplasmic proteins. ○, Cytoplasmic proteins; ■, ribosomal RNA; ▲, DNA.

Fig. 2. Hydrolysis of radioactive rat liver DNA with DNase and *Crotalus adamanteus* venom. The solution of hydrolysed DNA (from a rat kept 2 months after injection of tritiated DAB) was submitted to paper chromatography in methanol-ethanol-concentrated hydrochloric acid-water (50:25:6:19) by volume. The chromatogram was cut into 1 cm strips, eluted with normal hydrochloric acid, and the optical density at 260 m $\mu$  (—) and the radioactivity (---) were measured.

those reported earlier for male hooded rats with transplanted hepatomata<sup>1</sup>.

For DNA, however (Fig. 1), the specific activity dropped initially by about half between day 2 and day 7, and the level of binding then remained constant for 3 months. This latter level was of the order of 9  $\mu$ moles/g DNA or 3  $\mu$ moles drug/mole phosphorus. At this time (and for weeks before this) no radioactivity could be detected on the rRNA or on the proteins. The counts associated with DNA were highly significant above background, being about 3,000 c.p.m./mg DNA against a background of about 40 c.p.m.

The radioactivity associated with DNA at all times after injection was due to covalently bound metabolites and not to adsorbed dye, to adsorbed metabolites, or to the spurious incorporation of small metabolites such as tritiated water into the natural bases during synthesis. These points were established by hydrolysing the DNA to nucleosides with DNase I followed by *Crotalus adamanteus* venom, when it was shown that radioactivity could still not be extracted with benzene or ether. Paper chromatography followed by assay of radioactivity and ultra-violet determination showed that radioactivity could not be superimposed over the natural bases (Fig. 2). Furthermore, when DNA was hydrolysed with DNase followed by normal hydrochloric acid at 100° C for 1 h, about 40 per cent of the radioactivity could be extracted from the hydrolysate with benzene. A further 30 per cent was extracted when the solution was made alkaline with solid potassium hydroxide, and the remainder when the pH was adjusted to 7. Similar findings were obtained whether DNA was used from animals 2 days or 3 months after dosing. These experiments establish that some reactive metabolite or metabolites of [<sup>3</sup>H] DAB were covalently bound to liver DNA *in vivo*, and that the binding was labilized by hot normal hydrochloric acid.

Because of the relatively low specific radioactivity of the DNA compared with the proteins at early times after injection of tritiated butter yellow, the possibility that the radioactivity apparently associated with DNA was due to

the presence of up to 2 per cent residual protein could not be completely precluded in earlier investigations<sup>1</sup>. Our investigations make this possibility far less likely unless one postulates the presence of a protein intimately associated with DNA which is reactive towards the drug metabolites and which has a half life far in excess of normal. No evidence is at present available to indicate the existence of such a protein, the rate of turnover of histones for example normally being as high as or higher than that of other proteins<sup>3</sup>.

The mitotic index for liver cells is about 0.005–0.01 per cent<sup>4</sup> and if animals are fed only a maintenance diet as in the present experiment this rate is cut down even further<sup>5</sup>. Hence the cell divisions occurring during the 3 month period would be minimal. The present results therefore support the concept that the DNA in differentiated liver cells not undergoing division is not repaired or is repaired only slowly after modification by covalent interaction with foreign molecules of this kind. In some respects, this is surprising in view of the data of Pelc<sup>6</sup>, who has postulated, on the basis of short-term experiments, a half-life for mouse liver DNA of 13–58 days. On the other hand, Fresco and Bendich<sup>7</sup> incorporated tritiated thymidine into rat liver following partial hepatectomy and found little reduction in the specific radioactivity of the DNA during 3 months, from which they concluded that the DNA of resting rat liver is not being continuously renewed. The results of certain biological experiments are best interpreted on the basis of the latter conclusion, in so far as latent lesions in the form of covalently bound metabolites, or bases altered by the action of radiation, can remain associated with liver DNA for considerable periods of time. Thus Maini and Stitch<sup>8</sup> observed chromosomal abnormalities in the dividing liver cells of partially hepatectomized rats fed six months earlier on a diet containing the hepatocarcinogenic 3'-methyl analogue of butter yellow. In a similar context, Curtis and Crowley<sup>9</sup> and Stevenson and Curtis<sup>10</sup> showed that in mice after a single dose of X-rays many more chromosomal aberrations were present in subsequently dividing cells than in controls and that there was little decrease in the frequency of aberration during several months, indicating the absence of efficient systems for repairing this particular type of lesion in the DNA of non-dividing liver cells.

The implication of the present results is that DNA in the liver of male hooded rats can exist in combination with covalently bound butter yellow metabolites for long periods of time. Only during subsequent cell division does the latent damage manifest itself as chromosome aberrations and hence possibly mutation. This is consistent with the concept of latent period in carcinogenesis, and also with the view that an essential step in chemical carcinogenesis involves a critical level of chemical combination with DNA followed by cell divisions, the latter allowing the necessary processes of selection to occur.

Experiments are in hand to examine in a similar manner other liver carcinogens, such as  $\beta$ -naphthylamine in the mouse, and other reactive non-hepatocarcinogens such as the bifunctional alkylating agents.

We thank Sir Alexander Haddow and Dr. L. A. Elson for their interest. This investigation was supported by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council and the British Empire Cancer Campaign for Research, and by a grant from the National Cancer Institute, U.S. Public Health Service.

# Structure and Activity in Molluscicides

by

J. P. de VILLIERS  
M. M. ROSSOUW

National Chemical Research Laboratory,  
Council for Scientific and Industrial Research,  
Pretoria, South Africa

The search for molluscicides has revealed a variety of simple amides which, although not as toxic in small quantities as other molluscicides, are cheap and not poisonous to people.

THE importance of molluscicides as a means of controlling the part played by snails in the cycle of bilharzia is well established. Recent reviews<sup>1,2</sup> have dealt with various molluscicides and have also emphasized the importance of bilharzia as a parasite disease in man. The selection of compounds for testing as molluscicides has been virtually random, but recently attempts have been made to establish more rational procedures<sup>3,4</sup>.

In a previous study<sup>4</sup>, organic sulphydryl reagents were investigated and the theory used to predict lachrymatory activity was used to predict molluscicidal properties. This line of development was sufficiently promising to lead to a wider interest in compounds showing lachrymatory activity, so that, when Punte and co-workers<sup>5</sup> reported the intense lachrymatory activity of aerosol sprays of pelargonyl morpholide, compounds of this type were included in surveys of molluscicides.

Under the standard conditions described previously<sup>4</sup>, *Bulinus tropicus* was exposed to test solutions for 1,000 min and then allowed a recovery period of 24 h. It was found that pelargonyl morpholide (nonanoyl morpholide) was itself inactive as a molluscicide, but that the dodecanoyl and tetradecanoyl morpholides had considerable molluscicidal activity. Investigation of a variety of amides showed that the unsubstituted amides were inactive, as were those with only one substituent on the amide nitrogen. Amides with two substituents on the amide nitrogen such as dimethyl, diethyl, or the piperidides, morpholides or pyrrolidides have little or no molluscicidal activity when the acid moiety is decanoyl or smaller. The molluscicidal activity increases, however, to a maximum between dodecanoyl and tetradecanoyl and then rapidly disappears with a further increase in chain length. Fig. 1 shows the change in toxicity with increasing chain length for a number of disubstituted amides. Molluscicidal activity is thus a common property to a number of disubstituted amides, but is limited to only a few members of each homologous series.

Initially, only amides from the common even membered fatty acids were tested, but because maximum toxicity was found with either a twelve or fourteen carbon chain, a number of amides of tridecanoic acid was synthesized and found to be slightly more toxic than the amides of the two adjacent acids. The values for the tridecanoyl amides are included in Fig. 1 and it can be seen that they fall on the curves of toxicity for the even membered amide series. It is a common phenomenon for the biological activities of derivatives of homologous fatty acids to reach a maximum in the region of twelve carbon atoms. This has been commented on<sup>6</sup> and exploited commercially.

On investigating further structural variations, it was found that the molluscicidal activity of *N*-ethyl, *N*-dodecyl acetamide ( $LC_{50}$  2.5 p.p.m.) was similar to that of the isomeric *N*-diethyl dodecanoyl amide ( $LC_{50}$  3.0 p.p.m.). Also, the toxicity of the branched chain compound 2-*n*-butyldecanoyl morpholide ( $LC_{50}$  4.5 p.p.m.) was not very different from that of the isomeric straight-chain tetradecanoyl morpholide ( $LC_{50}$  3.0 p.p.m.).

Two series of esters, the methyl esters and the ethoxyethyl esters of the normal fatty acids, were investigated

for molluscicidal properties, but no member of either series had appreciable molluscicidal activity.

All the various results previously given can best be explained by postulating that these molluscicides are toxic because of a physical interference with the properties of membranes or interfaces within the snail and not because of any chemical reaction. For optimum effect, structure, molecular size and solubility relationships would thus be of great importance. The lack of activity of the unsubstituted or mono-substituted amides is probably a result of the influence of hydrogen bonding on the physical properties of the compounds and the lack of toxicity of the esters either to their rapid degradation or to different water solubilities.

The postulate of a physical rather than a chemical mechanism of toxicity for the amide molluscicides is further strengthened by their remarkably reversible action, as repeated washing of moribund snails with fresh water frequently leads to their recovery.

The active amides all have low water solubilities and the snails concentrate the molluscicide out of aqueous solution. Over considerable variations of time, 4–21 h, and of concentration, the exposure time multiplied by the

Fig. 1. Variation of toxicity with acyl chain length for a number of disubstituted amides.

$LC_{50}$  is a constant which implies that the uptake of molluscicide by the snail is directly proportional to the concentration in the test solution and that the snail possesses no rapid detoxifying mechanism.

These amide molluscicides can be considered as very water insoluble non-ionic surface active agents with a lyophilic chain of ten to sixteen carbon atoms and a somewhat hydrophilic grouping in the disubstituted amide grouping at the one end.

Berrie and Visser<sup>7</sup> claim to have isolated a substance excreted by a natural population of the snail *Biomphalaria sudanica*. This substance has an inhibiting effect on the growth of the snail and, if its concentration in the water is increased, it becomes lethal. The substance was identified as a mono-hydroxy tricarboxylic acid mono-isodecyl dimethyl ester. It could be expected to have the physical properties of a very water insoluble non-ionic surface active agent and could be very similar in physical properties to the amide molluscicides. Visser<sup>8</sup> recognized the surface active properties of the compound and proceeded to test a wide variety of detergents of all types.

From limited trials conducted with *Tilapia mossambica*, it would seem that the amide molluscicides are toxic to

fish. They have, however, extremely low oral toxicity to rats, as a dose of 2 g/kg body weight elicited no reaction. Pelargonyl morpholide is an extremely irritant oil, but the compounds with molluscicidal activity have no irritant properties at all.

The amide molluscicides are by no means the most effective molluscicides available when judged on a basis of their  $LC_{50}$  values. Because the effect of these molluscicides in a linear function of time and concentration, however, where prolonged dosing is possible very low concentrations can be used. The low cost and negligible mammalian toxicity of these molluscicides, coupled with their ease of manufacture and handling, undoubtedly make them most attractive for further investigation on a large scale.

## Polarization of Cosmic X-Rays

by

A. A. KORCHAK

Institute of Terrestrial Magnetism,  
Academy of Sciences,  
Moscow

The extent to which cosmic X-rays are polarized may provide information about the mechanism producing them, and the region from which they come. In this article the polarized X-rays produced by the bremsstrahlung mechanism are considered.

CONTINUOUS cosmic X-rays may be produced by one or all of three mechanisms—bremsstrahlung (thermal and non-thermal), synchrotron radiation and the inverse Compton effect. The polarization of cosmic X-rays may help to identify which mechanism is responsible, and thus to obtain information about the region from which the radiation comes. Dolan<sup>1</sup> has investigated polarization for the three mechanisms, and concluded that the observation of high polarization of X-rays means that the radiation is either (1) synchrotron, or (2) bremsstrahlung radiation of electrons the velocity vectors of which are non-isotropic. In this article the second possibility is considered; it is probably realized in solar flares, and possibly in some other sources of X-rays.

For a parallel mono-energetic beam of electrons of low energy, the degree of linear polarization is given by<sup>2</sup>

$$\Pi = \frac{\sigma_1 - \sigma_2}{\sigma_1 + \sigma_2} = \frac{B \sin^2 \theta}{B \sin^2 \theta + C} \quad (1)$$

where  $\sigma_1$  and  $\sigma_2$  are the bremsstrahlung cross-sections for the photons polarized perpendicular and parallel to the  $(\vec{p} \vec{k})$  plane, where  $\vec{p}$  and  $\vec{k}$  are electron and photon momenta, with the angle between  $\vec{p}$  and  $\vec{k}$  given by  $\theta$  and  $B$  and  $C$  given by

$$B = (3x - 2) \ln \frac{1 + \sqrt{1-x}}{1 - \sqrt{1-x}} + 6 \sqrt{1-x}$$

$$C = 2(2-x) \ln \frac{1 + \sqrt{1-x}}{1 - \sqrt{1-x}} - 4\sqrt{1-x} > 0 \quad (2)$$

where  $x = E_\gamma/E_K$  and  $E_\gamma$  is the photon energy. Equation (1) is obtained from a Born approximation for an unpolarized beam of electrons, and neglects screening. From equations (1) and (2) it follows that in the region of soft photons ( $x \ll 1$ ),  $B < 0$ , and  $|B| < |C|$ , so that  $\Pi > 0$ , that is, photons are polarized mainly in a direction

perpendicular to the plane  $(\vec{p} \vec{k})$ . In the region of hard photons ( $x \lesssim 1$ ),  $B > 0$  and  $\Pi < 0$ , that is, photons are polarized preferentially in the  $(\vec{p} \vec{k})$  plane. With the increase of photon energy, polarization changes from +1 to -1, passing through zero with  $x \approx 0.12$  regardless of the angle  $\theta$ .

Polarization is zero if the direction of movement of the electron coincides with the line of sight, and it reaches a maximum for electron beams perpendicular to the line of sight.

Increase in electron energy displaces the zero point to the region of harder photons and, at the limit when  $E_K \gg mc^2$ , negative polarization disappears<sup>3-5</sup>. The transition through zero values is a typical peculiarity of bremsstrahlung, which allows this radiation to be distinguished from synchrotron radiation. It is known that polarization of synchrotron radiation depends much less on frequency, and the direction of the predominant electric vector oscillation is always perpendicular to the projection of the magnetic field on the pictorial plane<sup>6</sup>. Under real astrophysical conditions, however, accelerated electrons may possess some energetic and angular distribution. The averaging of these distributions can change both the properties and the value of the polarization.

The simplest way of investigating the influence of the energy distribution on the polarization value may be most simply defined by the power energy spectrum  $E_K^{-\alpha}$ . If the spectrum of electrons extends in the non-relativistic region up to some energy  $E_{K0}$ , for a parallel beam of electrons  $\Pi$  will be defined by equation (1) as before.  $B$  and  $C$ , however, are now the functions of  $x$  and  $x_{K0} = E_\gamma/E_{K0}$  and are expressed by a hyper-geometrical function. With a steep spectrum of electrons ( $\alpha \gg 1$ ),  $\Pi$  is again equal to zero when  $x_{K0} = 0.12$ , and for the limiting values of very soft and very hard photons it reaches 100 per cent for large values of the angles  $\theta$ . As  $x$  decreases, the zero point is displaced towards the region of harder photons, and disappears

when  $\kappa \leq 1$ . This peculiarity of polarization remains in energetic distribution, and is different from the power law one shown, for example, in an exponential distribution (see, for example, ref. 1).

The angular distribution affects the value of the polarization much more than does an energetic one. For a sinusoidal distribution according to  $\sin^n \alpha$ , where  $n$  is a constant and  $\alpha$  the angle between the direction of motion of the electron and the axis of symmetry of the angular distribution (for example,  $H$ ), the degree of linear polarization of non-relativistic electrons is

$$\Pi_{n=2} = \frac{B \sin^2 \theta_0}{4B + 5C - B \sin^2 \theta_0}$$

$$\Pi_{n=4} = \frac{B \sin^2 \theta_0}{3B + 3.5C - B \sin^2 \theta_0} \quad (3)$$

where  $B$  and  $C$  are defined by equation (2) as before and  $\theta_0$  is the angle between the axis of symmetry of the angular distribution and the line of sight. It follows from equation (3) that with the sinusoidal angular distribution, the degree of polarization is much smaller than for the parallel beam of electrons (see equation 1), but increases with the growth of  $n$  (degree of anisotropy), reaching 50 per cent with  $n = 4$ , in the region of hard photons. Soft photons are polarized in the plane, passing through the axis of the angle distribution symmetry and the line of sight, and  $\Pi$ , as before, passes through the zero with  $E_\gamma \approx 0.12 E_K$  ( $B = 0$ ) regardless of the angle  $\theta_0$ . The simultaneous averaging by the angular and energetical distribution makes the maximum polarization even smaller. It is not difficult to investigate such a distribution for separate cases, making use of the assumption that the angular and energy distributions are independent. There is appreciable polarization (with  $\kappa = 6$  and  $n = 4$   $\Pi = 10 - 30$  per cent) only when the energy spectrum is rather steep and reaches the region where  $E_K \ll mc^2$ . The maximum polarization of bremsstrahlung might therefore be expected for parallel beams of accelerated electrons, for which the energy spectrum extends to the region of small energies of up to  $E_{K0} \approx mc^2$  (minimum ionization losses) or even up to the non-relativistic region. These two conditions can be realized primarily in solar flares. Another different case, which is also of interest, occurs when accelerated electrons are caught by a strong regular field in a trap and an anisotropic angular distribution is established in it as, for example, the belts of radiation around the Earth and Jupiter show.

Relativistic electrons accelerated in a flare will simultaneously produce bremsstrahlung, synchrotron and Compton radiation. It is not difficult to see, however, that in the X-ray region of the spectrum there is always a range of photon energies in which bremsstrahlung radiation will be predominant. This region is illustrated in Fig. 1, which shows the power spectrum of  $P/N_e$  radiation, where  $N_e$  represents a whole number of electrons  $\varphi$ . The solid lines are constructed for a spectrum of electrons with a single energy  $E_{K0} = 5 \times 10^6$  eV, and the dotted ones for the power spectrum with  $\kappa = 3$  in the region  $E_K \geq E_{K0}$ , and

$$N_e \propto \frac{1}{(\kappa - 1) E_{K0}^{\kappa-1}}$$

The curves are calculated from the formulae given in ref. 6 for the following values of the parameters in the region of radiation: mean concentration of gas  $n_i = 10^{12}$  cm $^{-3}$ , mean concentration of thermal photons  $n_{ph} = 10^{13}$  cm $^{-3}$  (radiation density  $W_{ph} = 4$  erg/cm $^3$ ,  $T = 6 \times 10^3$  °K) and the magnetic field  $H_1 \approx H = 10^2$  oersted. The maximum of synchrotron radiation occurs in the radiowave region of the spectrum at a frequency  $\nu_s \approx 4 \times 10^{10}$  c/s, the maximum of Compton radiation  $\nu_K$  occurs in the X-ray region at a frequency of about  $4.8 \times 10^{16}$  c/s ( $\lambda \approx 62$  Å), and the spectrum of bremsstrahlung increases logarithmically with frequency up to the energy of photons

Fig. 1. Power spectrum of  $P/N_e$  radiation, where  $N_e$  represents a whole number of electrons. A, Synchrotron; B, Compton; C, bremsstrahlung; a,  $\nu^{-1}$  ( $\kappa = 3$ ); b,  $\nu^{-2}$  ( $\kappa = 3$ ); c,  $\nu^{-1}$  ( $\kappa = 3$ ).

$E_\gamma = E_{K0} = 5 \times 10^6$  eV, and then falls steeply according to the law  $\nu^{-2}$ .

Fig. 1 shows that synchrotron radiation will predominate in the X-ray region of the spectrum  $E_\gamma \geq 1$  keV only if  $\kappa < 4$ , and the energy spectrum of electrons continues with a constant slope up to very high energies (for  $H = 10^2$  oersted, up to  $5 \times 10^6$  eV). This is not impossible, but it is scarcely probable, because of the rapid increase of energy losses with the increase of energy. Therefore for a steep energy spectrum in the region of large energies, the two other mechanisms will prevail in the X-ray region: for soft photons, the inverse Compton effect; and for hard photons, bremsstrahlung. Using values of the parameters  $n_i n_{ph} \approx 10^{12}$  cm $^{-3}$  and  $\kappa = 3$  the maximum Compton radiation is five times greater than the maximum bremsstrahlung radiation in the range of photon energies 0.01–4 keV.

For  $n_i = n_{ph} = 10^{12}$  cm $^{-3}$  and  $E_{K0} = 5 \times 10^6$  eV the integral total bremsstrahlung radiation is one thousand times greater than the Compton radiation. Because of a sharp maximum in the spectrum, however, there is an excess region of Compton radiation. The objections to the Compton mechanism in ref. 7 are therefore unconvincing.

The location of the three curves in Fig. 1 relative to each other is defined by the physical conditions in the radiating region,  $n_i$ ,  $n_{ph}$  and  $H$ , as well as by the properties of the accelerating mechanism,  $\kappa$  and  $E_{K0}$ .

It is not difficult to imagine the curve distribution using values of the parameters different from those in Fig. 1. The position of the maximum of synchrotron radiation is proportional to  $H_1 E_0^2$ , and its value is fixed by the magnetic field which is proportional to  $H_1$ . The location of the maximum of Compton radiation is proportional to  $T E_0^2$ , and its value is fixed by the mean concentration of thermal photons. If  $E_{K0}$  decreases, the power of the Compton and synchrotron radiation in the X-ray region  $E_\gamma \geq 1$  keV does not increase significantly, while bremsstrahlung radiation increases rapidly in proportion to  $E_{K0}^{(1-\kappa)}$  and becomes predominant throughout the X-ray region of the spectrum.

While the observations are being made, it is desirable to measure the degree of polarization in at least two regions of photon energy, for example with  $E_\gamma = 4$  keV and 20 keV. If the energy spectrum of accelerated electrons falls sharply or shows a break in the region of  $E_{K0} \approx 10^6$  eV, then the direction of polarization should ideally be at the angle  $\pi/2$ . The observation of this peculiarity of X-ray photon polarization will undoubtedly indicate bremsstrahlung radiation, and will enable subcosmic electrons in the atmosphere of the Sun and in other sources of X-rays to be investigated.

## LETTERS TO THE EDITOR

## ASTRONOMY

## Linear Polarization of Radio Sources at a Wavelength of 21.3 cm

THE Cambridge One-Mile radio telescope<sup>1</sup> has recently been used to make high resolution observations of a number of radio sources (refs. 2 and 3, and Macdonald, G. H., in preparation). Observations of the Crab Nebula, Cygnus A and the sources 3C 47, 103, 332, 338 and 4C 29.41 have been repeated with the receiving horns of the telescope set at 90° to their original direction, thus providing maps of these sources at two perpendicular polarizations; although these maps do not allow the unique distribution of polarization across the sources to be obtained, the results are nevertheless of some interest.

For each source observations were made for 12 h periods at either four or eight positions of the moving aerial according to the angular extent of the source<sup>4</sup>; the instrument had a pencil-beam response in the neighbourhood of the source with half power beam-widths of 23" arc in right ascension and 23" cosec  $\delta$  in declination. The receiving horns were set at position angles (measured from north positive through east) of 0° and 90°, respectively; maps of the sources at the two polarizations were then compared enabling information about the distribution of polarization across the sources to be obtained.

The main source of error in these observations is likely to be uncertainty in the calibration of the contour levels in the two maps which may be as great as 5 per cent in some cases; uniform polarization across the whole source can then not be recognized except in those cases where earlier observations have provided values for the total polarization of the source.

(a) *The Crab Nebula.* The overall polarization of the Crab Nebula at  $\lambda = 21$  cm has been found<sup>5</sup> to be 1.6 per cent  $\pm 0.1$  per cent with a position angle of  $86^\circ \pm 2^\circ$ . Because this position angle is very close to one at which measurements were made in the present observations it has been possible to eliminate some of the uncertainty in the calibration of the contour levels by scaling the map of the Crab Nebula at one polarization so that the overall polarization becomes 1.6 per cent when the two maps are compared. The map of the Crab Nebula for position angle 0°, which has already been published<sup>6</sup>, is shown in Fig. 1; the map for position angle 90° is remarkably similar, and in particular the features of emission marked A, B and C in Fig. 1 and which correspond well to similar features in the optical continuum emission from the nebula remain virtually unchanged at both radio polarizations.

By comparing the intensities in the maps at the two polarizations the following deductions can be made: (1) There are no strongly polarized regions of small angular size within the nebula because any region  $\sim 20''$  arc in extent and with a degree of polarization greater than 3 per cent would have been detected; the small mean polarization observed for the nebula is therefore not, as in the optical case, made up of the sum of a number of strongly polarized components. (2) The polarized radiation is confined to an area some 2' arc in diameter near the centre of the nebula over which the polarization is fairly uniform; this conclusion agrees with that previously reached by Davies *et al.*<sup>7</sup>. Over most of the central region

of the nebula the degree of polarization is between 2 per cent and 3 per cent, but the polarization reaches 5 per cent  $\pm 2$  per cent near point A (Fig. 1). (3) There is little correspondence between radio and optical polarization features; in particular there are no anomalous features in the radio polarization in regions where locally there are large changes in the magnitude and direction of the optical polarization. (4) In the outer regions of the nebula no significant polarization is detectable.

It should be noted that Kronberg<sup>8</sup> has observed the Crab Nebula at  $\lambda = 21$  cm with two aerials at a fixed spacing of  $\sim 2,000\lambda$  and concluded that there is a point source with a flux-density of  $(7.5 \pm 1.6) \times 10^{-26}$  m.k.s.  $\sim 1.5'$  arc north-west of the centre of the nebula; this flux-density is about 0.9 per cent of the total from the nebula. This conclusion is clearly incompatible with the present observations which use a range of aerial spacings up to  $7,000\lambda$  and show no evidence in this area for any source having an angular size  $< 15''$  arc and with a flux-density greater than 0.2 per cent of the total from the nebula. Structure  $\sim 30''$  arc is, however, clearly present at several places within the nebula but none contributes more than 0.2 per cent of the total flux-density; furthermore, an upper limit of 0.1 per cent can be put on the flux-density at  $\lambda = 21$  cm of any point source at the centre of the nebula where the low-frequency point source appears to lie<sup>9</sup>. This result is discussed further in the accompanying communication by Bell and Hewish<sup>10</sup>.

Fig. 1. Map of the Crab Nebula with electric vector in position angle 0°; co-ordinates are 1950.0 and the contour interval is 1,300° K. Regions A, B and C correspond to similar features in the optical continuum radiation from the nebula.

(b) *Cygnus A.* Maps of the source obtained in the present observations are shown in Fig. 2, and cuts along the major axis are shown in Fig. 3. It can be seen that there is virtually no integrated polarization in the source as has previously been shown by Morris and Radhakrishnan<sup>11</sup>; there does, however, appear to be significant polarization in the "bridge" between the two components, the degree of polarization apparently reaching  $\sim 20$  per cent in this region.

It has been suggested<sup>12,13</sup> that for Cygnus A the observed dependence of overall polarization on wavelength results from the effects of differential polarization between the two main components of the source. The present results show that these two components are effectively unpolar-

ized at  $\lambda = 21$  cm. A possible explanation is that Cygnus A has a very large rotation measure and depolarization occurs as a result of differential Faraday rotation over a scale of  $\sim 20''$  arc; such depolarization can presumably only occur in the vicinity of the source, because if it were galactic in origin implausibly large changes in the total rotation would have to occur over very short distances within the Galaxy<sup>12</sup>. An alternative possibility is that most of the polarization previously measured at wavelengths less than 6 cm also comes from the "bridge" region; the depolarization of the source between  $\lambda = 3$  cm and  $\lambda = 21$  cm may then be explained if the polarized "bridge" region had a somewhat flatter spectrum than the source as a whole, although this simple mechanism does not readily account for the pronounced maximum which is believed to occur in the degree of polarization around  $\lambda = 3$  cm (ref. 13).

(c) 3C 47. This source consists of two components separated by  $62''$  arc and the line joining them has a position angle of  $30^\circ$ ; the south-west component is just resolved<sup>3</sup>. Measurements by Bologna *et al.*<sup>14</sup> have shown

Fig. 2. Maps of Cygnus A at the two polarizations, the position angle of the electric vector being shown in the top left-hand corner of each map; co-ordinates are 1950.0 and for each map the contour interval is 30,000 K. The positions of optical galaxies associated with the source are shown by two crosses.

Fig. 3. Sections along the major axis of Cygnus A at the two polarizations; the co-ordinates (1950.0) of the peaks of maximum brightness are indicated. The standard error in the calibration of the brightness scale for each polarization is approximately 4 per cent. Position angle: —●—,  $90^\circ$ ; —,  $0^\circ$ .

Fig. 4. Sections along the major axis of 3C 47 at the two polarizations; the co-ordinates (1950.0) of the peaks of maximum brightness are indicated. The standard error in the calibration of the brightness scale for each polarization is approximately 4 per cent. Position angle: —●—,  $0^\circ$ ; —,  $90^\circ$ .

that the polarization at  $\lambda = 21.2$  cm is  $2.4$  per cent  $\pm 1.6$  per cent with a position angle of  $4^\circ \pm 21^\circ$ ; the present observations are consistent with these results, and profiles of the source along the major axis at the two polarizations are shown in Fig. 4. The south-west component shows about 7 per cent polarization, and it also appears that the north-east component is polarized but with a significantly different position angle from that of the south-west component.

Source	Structure <sup>3,4</sup>	Components	Polarization of component (per cent)	Position angle of feed for which component has greatest amplitude
3C 47	Two components, the S.W. component being just resolved; separation of the components $62''$ arc.	N.E.	$3 \pm 3$	$90^\circ$
		S.W.	$7 \pm 3$	$0^\circ$
3C 103	Two unresolved components with a separation of $88''$ arc.	N. leading	$1 \pm 3$	$0^\circ$
		S. following	$2 \pm 3$	$90^\circ$
3C 332	Two components each $< 15''$ arc in diameter; separation of the components $54''$ arc.	N. following	$0 \pm 4$	—
		S. leading	$1 \pm 4$	$90^\circ$
3C 338	Two components approximately E.-W. each with complex structure; separation of the components $41''$ arc.	W.	$0 \pm 3$	—
		E.	$0 \pm 3$	—
4C 29.41	Two components, the E. component unresolved and the W. component extended. Separation of the components $50''$ arc.	W.	$5 \pm 4$	$90^\circ$
		E.	$0 \pm 4$	—

(d) 3C 103, 332, 338 and 4C 29.41. Each of these sources consists of two components<sup>3,4</sup>, although in some cases the individual components have resolved features. In no case has significant polarization been detected in the present observations in any part of these sources; details of the measurements made including the results for 3C 47 are given in Table 1. It should be noted that the source 3C 338 has been observed by Bologna *et al.*<sup>14</sup> at  $\lambda = 21.2$  cm to have a polarization of  $3.5$  per cent  $\pm 0.7$  per cent with a position angle of  $57^\circ \pm 6^\circ$ ; this measurement is consistent with the present observations because any polarization with position angle between  $35^\circ$  and  $55^\circ$  is virtually undetectable in measurements at the two position angles used in the present observations.

I thank Dr. Ann C. Neville for the preparation of the source maps, and the Royal Commission for the Exhibition of 1851 for a senior studentship.

### Position of the Low Frequency Radio Source in the Crab Nebula

RECENT radio observations of the Crab Nebula<sup>1-3</sup> have demonstrated the existence of a component of small angular diameter which contributes a significant fraction of the total flux density at frequencies of less than about 100 Mc/s. The high brightness temperature deduced from the interplanetary scintillation of this source at 38 Mc/s (ref. 3) makes it difficult to attribute this radiation to the synchrotron process, and coherent radio emission from a dense plasma associated with the star has been suggested as a possible mechanism. The previously reported position for the small diameter source based on a lunar occultation observed at 26.5 Mc/s (ref. 2) lies about 1.2' arc from the centre of the nebula, however, and is well removed from the centre of the observed expansion. The present observations show that the position of this source in the nebula must be much nearer the centre than the earlier measurement suggests.

The method used here exploits the fact that only the small component of the nebula exhibits interplanetary scintillation. By observing the magnitude of (a) the total signal and (b) the scintillations on the record obtained with a phase switching interferometer, it is possible to determine the difference in phase of the two interference patterns (Fig. 1) and thus the difference in position of the small source and the centroid of the brightness distribution of the nebula. The method avoids the need for correcting for ionospheric refraction and does not involve any other calibration of the instrument.

The measurements were carried out at a frequency of 81.5 Mc/s using the Cambridge interferometer<sup>4</sup>, which has recently been converted to this operating frequency. This aerial system, which could previously observe a source only near its meridian transit, has also been modified to allow its response to track a source over a limited angle. For the present observations this extended the time for which radiation from the Crab Nebula could be recorded from about 5 min to about 20 min per day.

For measurement of position in right ascension the west half of the long cylindrical paraboloid (725 ft. × 65 ft.) was used in conjunction with the shorter movable aerial (190 ft. × 65 ft.) as an interferometer with an east-west baseline of 244λ at 81.5 Mc/s. Two pairs of phase-switching receivers were used in order to record "cos" and "sin" components corresponding to interference patterns in quadrature<sup>5</sup>.

In order to observe the small scintillating component of the signal alone, the receiver output was passed through a filter which removed from the records components with frequencies less than about 0.16 c/s. The rapidly varying scintillations which remained were amplified and recorded separately. The scintillation amplitudes are modulated by the "sin" and "cos" responses to the small diameter source in the usual way and a comparison of the relative sizes of individual maxima on the two records can be used to derive the phase of the envelope (Fig. 1c and d). The direct record (Fig. 1a and b) is little affected by the presence of the small diameter source, which contributes 5-10 per cent of the total signal. Because the source is not appreciably resolved at the baseline used, the relative phases of the direct record and the envelope of the filtered record make it possible to find the position of the compact component relative to the whole source.

From observations made on July 16, 17 and 18, 1966, the right ascension of the small component was found to coincide with the centroid of the total emission to an

Fig. 1. Receiver output obtained with the 244λ east-west interferometer. Records a and b show the "cos" and "sin" components of the output. The high frequencies present on these records are shown amplified further as c and d.

accuracy of  $\pm 10''$  arc, the average position of the small source being  $1.0'' \pm 10''$  arc earlier.

For position measurements in declination, the west half of the long aerial was again used, this time in conjunction with a small aerial measuring 40 ft.  $\times$  40 ft., which could be moved to give a maximum separation of 840 ft. In this position the centres of the interferometer elements were separated by  $42\lambda$  in an east-west direction and by  $60\lambda$  in a north-south direction when observing at the declination of the Crab Nebula. The same receiving system and measuring technique were used as before. The final position derived from measurements made on July 23 and 24, 1966, was  $0.3' \pm 1.0'$  south of the centroid.

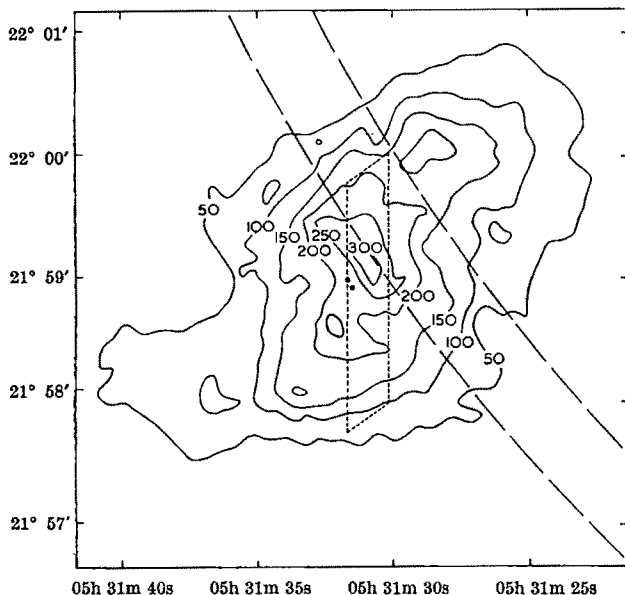

Fig. 2. The measured position of the X-ray source<sup>12</sup> (dotted area) and the low frequency radio source (parallelogram), superimposed on optical isophotes due to Woltjer<sup>13</sup>.

The accuracy of the relative position measurements in the two co-ordinates is limited mainly by the signal to noise ratio on the filtered scintillation records and is correspondingly worse for the declination measurements, which used a smaller effective collecting area as well as a shorter baseline. Position errors as a result of confusion might affect the apparent position of the centroid but not that of the small source. It is estimated, however, that confusion errors should be less than  $2''$  arc.

In order to establish the absolute position of the small component, it is necessary to find the co-ordinates of the centroid of the nebula at 81.5 Mc/s when observed with an interferometer of the resolution used. Recent observations<sup>6,7</sup> have not revealed any variation greater than  $10''$  arc in the position of the centroid for observing frequencies between 60 Mc/s and 456 Mc/s and give a position in good agreement with that derived from observations at 408 Mc/s with the Cambridge One-Mile telescope:

$$05h\ 31m\ 31.0s \pm 0.5s \quad 21^\circ\ 59.1' \pm 0.3' \quad (1950.0)$$

These observations also show that for an interferometer of up to  $500\lambda$  east-west baseline the centroid will be within  $0.2s$  of this position.

Using this position for the centroid, the derived final position for the small component is

$$05h\ 31m\ 30.9s \pm 0.8s \quad 21^\circ\ 58.8' \pm 1.0' \quad (1950.0)$$

This position agrees with that of the pair of  $15m$  stars near the centre of the Crab Nebula. Baade<sup>8</sup> found that the south preceding component of this pair has a proper motion agreeing well with that of the nebula, and a connexion appears likely, although Minkowski<sup>9</sup> found no

definite evidence that this star had passed through a supernoval phase. The position of this star is

$$05h\ 31m\ 31.46s \quad 21^\circ\ 58'\ 54.8'' \quad (1950.0)$$

Shklovsky<sup>10</sup> has already suggested that the low frequency radio source may be associated with the X-ray source which has recently been discovered in the Crab Nebula<sup>11</sup>. The only accurate measurement of the position of the X-ray source<sup>12</sup>, based on observation of a lunar occultation, shows that the source has a diameter of about  $0.5'$  arc to half power and is centred at least  $0.5'$  arc from the star. Measurements were only made at immersion and therefore only one position co-ordinate was determined. The position of the limb of the Moon when the half powers points of the X-ray source were being occulted is shown in Fig. 2 superimposed on the optical isophotes given by Woltjer<sup>13</sup>. The errors for the present measurement of the position of the low frequency source and the position of the pair of stars are also shown.

I thank Dr. A. Hewish and Professor Sir Martin Ryle for many helpful discussions, and also the Science Research Council for a research fellowship.

### Angular Size and Flux Density of the Small Source in the Crab Nebula at 81.5 Mc/s

THE existence of a source in the Crab Nebula with an angular diameter of less than  $1$  sec of arc has been revealed by observations of interplanetary scintillation at a frequency of 38 Mc/s (ref. 1). The brightness temperature derived from these observations is so great that the synchrotron mechanism may not provide an adequate explanation for the emission. The determination of the spectrum is therefore of great interest.

It has proved difficult in observations at other frequencies, based on lunar occultations and interferometers of high resolving power, to recognize the contribution from this very compact component in the presence of other fine structure within the nebula. Further observations of interplanetary scintillation at 81.5 Mc/s have therefore been made, first to enable the flux density to be determined at this frequency and second to derive a more accurate value for the angular diameter of the source.

The observations used in this investigation were made during about 60 days in the period March–July 1966 by means of one aerial and receiver of the solar wind experiment which has already been described<sup>2</sup>. A pen recorder with a time constant of  $0.3$  sec was used to record the scintillation which amounted to only a few per cent of the total deflexion.

The records were analysed to obtain daily values of the scintillation index  $I'$  (root mean square deviation expressed as a fraction of the mean) and in Fig. 1 the results are plotted as a function of the perpendicular distance ( $p$ )

of the line of sight to the source from the Sun. Each point is an average of observations made during 3 or 4 days. It can be seen that  $F$  reaches a maximum of 0.035 for  $p \sim 0.5-0.6$  A.U. and then decreases as the line of sight moves closer to the Sun. This systematic change of  $F$  with  $p$  is similar to that observed for 3C 138 at 178 Mc/s and the angular diameter can be estimated from the scintillation visibility ( $V$ ) as described by Little and Hewish<sup>3</sup>. In Fig. 2 the observed values of  $V$  (defined as  $F$  (observed)/ $F$  (ideal point source)) are compared with theoretical curves for a symmetrical gaussian source the intensity of which is assumed to be 10 per cent of that of the non-scintillating component. The angular diameter thus derived is found to be  $0.2'' \pm 0.1''$ . This value is somewhat greater than that derived from the earlier observations at 38 Mc/s; however, we believe it to be more accurate because it is based on a direct measurement of the scale of the diffraction pattern at the Earth. Previously, the scale was estimated from the angular spectrum of the scattered radiation assuming multiple scattering, but it is now known that scintillation corresponds to weak scattering beyond 0.5 A.U. at 81.5 Mc/s (ref. 4) and the same is probably also true at 38 Mc/s. A revised estimate of the angular diameter at 38 Mc/s, assuming the pattern to have the same scale at both frequencies, gives a value comparable with our present result. Until more is known about the diffraction pattern at 38 Mc/s there is no evidence that the angular diameter depends on frequency.

The estimated relative intensity of the small source is 10 per cent  $\pm$  1.5 per cent, the greatest uncertainty being caused by day to day changes in the irregularities of the interplanetary medium. The spectrum of the small source derived from the present estimate at 81.5 Mc/s and previous scintillation data at 38 Mc/s is shown in Fig. 3. The uncertainties are large, but at these frequencies the result is consistent with that suggested by Andrew *et al.*<sup>5</sup>. Because the position of the small source is now known to be near the centre of the nebula<sup>6</sup> the 26.5 Mc/s flux derived by Andrew *et al.* cannot be used to derive the spectrum below 38 Mc/s. At frequencies greater than 81.5 Mc/s sensitive measurements are required to detect scintillation and an earlier attempt at 178 Mc/s (ref. 7) was limited by inadequate sensitivity. In the accompanying note Branson<sup>8</sup> has presented his results of high resolution observations at 1,407 Mc/s which show that, in the position determined by Gower, there is no

Fig. 1. The scintillation index  $F$  of the Crab Nebula at 81.5 Mc/s as a function of distance from the Sun.

Fig. 2. The observed scintillation visibility  $V$  compared with theoretical curves for a symmetrical gaussian source of diameter: a,  $0.1''$ ; b,  $0.2''$ ; c,  $0.3''$ .

Fig. 3. The spectrum of a, the Crab Nebula; b, the compact source.

source with an angular size  $< 15''$  which contributes more than 0.1 per cent of the total flux from the nebula. This result, plotted in Fig. 3, shows that the spectrum must have a steep slope between 81.5 Mc/s and 1,407 Mc/s and differs from the spectrum derived by Kronberg<sup>9</sup>, who associated the emission from a component of the nebula with that from the compact low frequency source.

Calculations, following the method of Hornby and Williams<sup>10</sup> and using the revised angular diameter, lead to upper limits of  $3 \times 10^{-5}$  G and  $2 \times 10^{-7}$  G at 81.5 Mc/s and 38 Mc/s, respectively, for the field strength in the source if radiation by the synchrotron mechanism is

assumed. The corresponding minimum energies for relativistic electrons alone are then  $\sim 10^{47}$  ergs and  $\sim 10^{50}$  ergs. It is therefore difficult to account for the compact source by synchrotron radiation because this requires both an unreasonably small magnetic field and a minimum particle energy of the same order as that contained in the complete extended source.

One of us (S. J. B.) is indebted to the Northern Ireland Ministry of Education for a maintenance grant.

### Changes in Polarization, Light and Colour during the Outburst Stage of the Recurrent Nova *T* Pyxidis

We were notified on December 8, 1966, by Mr. Frank Bateson, of the discovery in New Zealand by Mr. Albert Jones that the recurrent Nova *T* Pyx was at visual magnitude 12.9 on December 7. Previous estimates had placed the nova near magnitude 14.5 for some years. Photometric and polarimetric observations, with the 40 in. and 24 in. reflectors at Siding Spring Mountain, began on the night of December 8-9. The photometric observations during the pre-maximum and maximum phases of the outburst are shown in Table 1 and in Fig. 1. The trends of the variation in visual magnitude, during the gaps in the observations caused by clouds at Siding Spring Mountain, are shown in Fig. 1 by broken curves and are based on visual observations by V. L. Matchett and M. Jones of the Moreton Bay Astronomical Club. A slight adjustment was necessary to bring the visual observations into agreement with the photoelectric results. Previous

Fig. 1. The light curve for *T* Pyx is drawn using visual magnitudes measured with the 40 in. (●) and 24 in. (○) telescopes at Siding Spring Observatory. The broken sections of the curve were obtained from measurements by V. L. Matchett and M. Jones of the Moreton Bay Astronomical Club.  $B-V$  (x) and  $U-B$  (•) values are plotted at the bottom of the diagram.

Fig. 2. *a*, The time variation of the percentage polarization,  $P(\%)$ , in the blue is shown for the pre-maximum and maximum phases of the outburst of *T* Pyx. *b*, The ratios of the amounts of polarization in the blue and ultra-violet (□) and in the blue and visual (▲) are plotted.

Fig. 3. The time dependence of  $\theta$ , the position angle of the electric vector (measured from north towards east) for the  $U$  (□),  $B$  (●) and  $V$  (▲) system of filters is shown.

outbursts of the nova were in 1890, 1902, 1920 and 1944 and the light curve in Fig. 1 is strikingly similar to those obtained in 1902, 1920 and 1944<sup>1</sup>.

The polarization observations were made with the new rotatable 24 in. telescope which had been put into service only a month before. It is very similar to that described by Hiltner and Schild<sup>2</sup>. A two-channel polarimeter was used with EMI 9524S photomultipliers and  $UBV$  filters.

These observations, which were the first to be made of any active nova, revealed that the light from *T* Pyx was linearly polarized and showed short period fluctuations in the degree, angle, and wavelength dependence of the polarization. The results are presented in Table 2 and in Figs. 2 and 3. A few polarimetric observations made with  $H\gamma$  interference filters show that the degree of polarization is about the same as with the  $B$  filters of the ( $UBV$ ) system and therefore the polarization of emission lines does not seem to be smaller than that of the continuum. This fact suggests that the polarization is produced in the outer shell of the nova, perhaps by scattering of light in the expanding gaseous envelope.

Observations of *T* Pyx are still in progress with the various types of equipment available at Mount Stromlo and Siding Spring Mountain, and we hope to continue them for several months when the nova

### A Search for the $\Lambda$ -Doublet Transition in the $^2\Pi_{1/2}$ , $J=1/2$ State of OH

RECENT radio astronomical investigations of the 18-cm ground-state  $\Lambda$ -doublet transition of the OH radical have suggested that maser amplification of the radiation is taking place in the interstellar medium. So far, no entirely

satisfactory theoretical explanation of the observations has been published. A number of workers (for example, Cook<sup>1</sup> and Litvak *et al.*<sup>2</sup>) have suggested that optical pumping of the OH molecule is responsible for the apparent population inversion. Another possibility is that the OH molecule is formed in an excited state in the vicinity of HII regions. In either case, an appreciable number of OH molecules may be found in excited levels. If the populations of the excited rotational levels of the ground electronic and vibrational state were sufficiently large, it would be expected that it would be possible to observe  $\Lambda$ -doublet transitions originating in these levels.

According to Dousmanis, Sanders and Townes<sup>3</sup>, the state  $^2\Pi_{1/2}$ ,  $J=1/2$ , which is a pure  $^2\Pi_{1/2}$  state, is weakly coupled to the lowest lying state of the molecule ( $^2\Pi_{3/2}$ ,  $J=3/2$ ), which is composed of a mixture of  $^2\Pi_{1/2}$  and  $^2\Pi_{3/2}$  wave functions. It is possible to estimate the transition time between these two states to be of order 10 sec. This time should be compared with the  $\Lambda$ -doublet transition time in the  $^2\Pi_{1/2}$ ,  $J=1/2$  state. The latter time is determined by the rate of stimulated emission and can be estimated with the aid of the Einstein  $A$  formulae for OH given by Turner<sup>4</sup>. It is found that the  $\Lambda$ -doublet transition time ( $t$ ) due to stimulated emission in the  $^2\Pi_{1/2}$ ,  $J=1/2$  state is  $t \approx 10^8/T_b$ , where  $T_b$  is equal to the brightness temperature at the  $\Lambda$ -doublet line frequency ( $\sim 4,717$  Mc/s) due to both continuum and line radiation. 18-cm OH emission has been observed in the vicinity of HII regions where  $T_b$  is typically  $\sim 100^\circ$  K. The  $\Lambda$ -doublet transition time is therefore a few orders of magnitude smaller than the transition time to the  $^2\Pi_{3/2}$ ,  $J=3/2$  state. Thus it would be expected that the  $^2\Pi_{1/2}$  state would have a considerably lower population than the ground state. Because of the unknown nature of the pumping mechanism in the ground state, however, it appeared worth while to look for the line at 4,717 Mc/s.

We used the 140 ft. telescope of the National Radio Astronomy Observatory (Green Bank, West Virginia) equipped with a parametric amplifier and with the Harvard University 21-channel spectral line radiometer. The total system temperature was approximately 600° K and all measurements were made with a frequency resolution of 30 kc/s. The  $^2\Pi_{1/2}$ ,  $J=1/2$   $\Lambda$ -doublet lines have never been observed in the laboratory. Their frequencies may be calculated by means of the theory of Dousmanis, Sanders and Townes<sup>3</sup>, combined with the values for the hyperfine coupling constants obtained by Radford<sup>5</sup>. The estimated maximum error in the calculated frequencies is  $\pm 6$  Mc/s.

Table 1. SUMMARY OF OBSERVATIONAL RESULTS

Source	Transition	Line frequency (Mc/s)	Frequency range (Mc/s) covered	$\Delta T/T_{1665}$
W3	$F=1 \rightarrow 1$	4,717.2	+6.1 $\rightarrow$ -7.1	0.013
W3	$F=1 \rightarrow 0$	4,702.3*	+4.5 $\rightarrow$ -8.1	0.020
W3	$F=0 \rightarrow 1$	4,807.5*	+9.7 $\rightarrow$ -8.9	0.020
W49	$F=1 \rightarrow 1$	4,717.2	+6.6 $\rightarrow$ -6.6	0.010
W49	$F=1 \rightarrow 0$	4,702.3*	+4.7 $\rightarrow$ -6.1	0.016
W49	$F=0 \rightarrow 1$	4,807.5*	+3.3 $\rightarrow$ -9.9	0.016

\* These frequencies differ slightly from those published by Barrett<sup>6</sup>.

Our observational results are summarized in Table 1. The  $^2\Pi_{1/2}$  lines were searched for, but not detected, in W3 and W49—two radio sources of known 18-cm OH emission. Our measured upper limit to the  $^2\Pi_{1/2}$  line strengths ( $\Delta T$ ) has been compared with the most intense<sup>6</sup> observed 18-cm radiation ( $T_{1665}$ ) from W49 and W3. The quantity of  $T_{1665}$  was obtained by integrating over 10 kc/s the 1,665 Mc/s profiles of Palmer and Zuckerman<sup>6</sup> (W49) and Barrett and Rogers<sup>7</sup> (W3), which were all obtained with the 140 ft. telescope. At 1,600 Mc/s, 10 kc/s in velocity space is equal to 30 kc/s at 4,800 Mc/s. The ratio  $\Delta T/T_{1665}$  is given in the last column of Table 1. In the fourth column in Table 1 we give the frequency range covered for each line relative to  $V = -45.5$  km/s in W3 and  $V = +16.2$  km/s in W49, where  $V$  is radial velocity with respect to the local standard of rest.

The present experiment has placed upper limits on the intensities of the  $^2\Pi_{1/2}$ ,  $J = 1/2$   $\Lambda$ -doublet lines; the upper limits are 1–2 per cent of that of the observed 18-cm  $\Lambda$ -doublet emission lines. If a better understanding of the 18-cm emission should make it possible to predict theoretically that the strength of the  $^2\Pi_{1/2}$  lines is of order of between ten and a hundred times weaker than the upper limits found in our observations, such an intensity should be observable once the  $^2\Pi_{1/2}$  line frequencies are measured in the laboratory.

We thank D. Smith and L. Bowles for their assistance with the equipment. Financial support for this investigation was provided by the U.S. National Science Foundation.

## PLANETARY SCIENCE

### Rates of Accumulation of Ferro-manganese Nodules

ALTHOUGH various models have been proposed to explain the origin of manganese nodules (see Goldberg and Arrhenius<sup>1</sup>), two major hypotheses have received extensive attention. One concept suggests that manganese nodules form as the result of interaction between submarine volcanic products and sea water<sup>2,3</sup>. The common association of manganese nodules with volcanic materials constitutes the main evidence for this theory. The second theory involves a direct inorganic precipitation of manganese from sea water. Goldberg and Arrhenius<sup>1</sup> view this process as the oxidation of divalent manganese to tetravalent manganese by oxygen under the catalytic action of particulate iron hydroxides. Manganese accumulation by the Goldberg and Arrhenius theory would be a relatively slow and comparatively steady process, whereas Bonatti and Nayudu<sup>3</sup> believe manganese nodule formation takes place subsequent to the eruption of submarine volcanoes by the acidic leaching of lava.

The measured rates of manganese nodule accumulation seem to support gradual accumulation. The first direct determinations were based on the decay of radium with depth in the nodule and gave values ranging from 0.7 to 65 mm/10<sup>3</sup> yr<sup>4-6</sup>. These measurements have been criticized<sup>1</sup> because much of the radium is probably ionium supported. The rates would therefore have to be lowered to 0.01 to 1.3 mm/10<sup>3</sup> yr<sup>6</sup>. The lower value agrees with the  $^{230}\text{Th}/^{232}\text{Th}$  determination of Goldberg<sup>7</sup> on the "Horizon"

nodule of 0.01 mm/10<sup>3</sup> yr. More recently, Bender *et al.*<sup>8</sup>, using the decay of ionium, determined the rate of accumulation in a north-western Pacific nodule to be approximately 0.003 mm/10<sup>3</sup> yr. Bonatti and Nayudu point out that the difficulty of such slow rates is that the nodules, in their opinion, would become buried because pelagic sedimentation rates are at least 100 times faster.

If the volcanic nuclei commonly found in manganese nodules are dated by the potassium argon method, a lower limit to the rate of manganese nodule growth can be determined. Assuming both a uniform and continuous growth of ferromanganese oxide, this rate is a measure of the growth of the ferromanganese oxide over the entire history of the nodule. We have determined rates by this method (Table 1) and compared them with the differential rates by the  $^{230}\text{Th}/^{232}\text{Th}$  method (Table 2) and the  $^{234}\text{U}/^{238}\text{U}$  disequilibrium method (Table 2). It should be noted that the potassium argon rates are calculated over the entire thickness of the nodules, while the rates calculated from the other two methods cover only the outermost few millimetres of the nodules.

Potassium and argon analyses were made on pure mineral separates from the volcanic cores of manganese nodules. Potassium was analysed by atomic absorption with a sodium buffer, and an isotope dilution analysis of the argon was made with an omegatron mass spectrometer. Thin layers of nodule were sampled with a dental drill for thorium and uranium analyses. Nodule material was dissolved with acidified hydrogen peroxide, and the experimental procedure of Goldberg and Koide<sup>9</sup> was followed for the determination of the  $^{230}\text{Th}/^{232}\text{Th}$  ratio.  $^{234}\text{U}/^{238}\text{U}$  ratios were determined by first coprecipitating the uranium with iron hydroxide. The ion exchange procedure of Korkish and Hazan<sup>10</sup> was then used for isolation of uranium which was measured by alpha-spectroscopy.

The  $^{230}\text{Th}/^{232}\text{Th}$  rates were corrected for uranium support by assuming equilibrium between ionium and uranium at depth in the nodule and a constant uranium concentration in a given nodule. Under these assumptions all of the  $^{230}\text{Th}$  found at depth in the nodule will be from uranium. The method of successive approximations is then used to determine the percentage of equilibrium attained by each sample from that nodule. The correction is then the total amount of  $^{230}\text{Th}$  from uranium multiplied by the fraction of equilibrium attained. The correction when applied to the data presented here reduces the rates of accumulation by a maximum of 25 per cent. The uranium concentration in a nodule may vary by a factor of two<sup>11</sup>. If the uranium concentration is doubled, the correction from uranium can reduce the rate by as much as 50 per cent of the uncorrected rate of the nodules analysed.

The  $^{234}\text{U}/^{238}\text{U}$  data also indicate a slow rate of deposition for ferromanganese nodules. The resulting rates are roughly the same as those determined by the  $^{230}\text{Th}/^{232}\text{Th}$  on the same nodule. It should be noted that the surface uranium ratios are the same within the limits of precision to previously determined ratios in sea water of 1.14 (refs. 12, 13). This, when coupled with normal decay toward equilibrium as one moves toward the centre of the nodule, is evidence for current growth of the nodules.

Three nodules, each having a volcanic nucleus which appeared to result from a single volcanic event, were selected for potassium argon dating. One of these nodules, the "Horizon" nodule, is among the largest in the Scripps collection. It consists of a 60-100 mm thick layer of ferromanganese oxide covering a predominantly phillipsite nucleus. Sufficient unaltered plagioclase for dating was easily separated from this latter material. The second nodule dated, DWHD 47, consists of a 5-10 mm ferromanganese oxide layer covering a light coloured nucleus. The nucleus has 200-300 micron size anorthoclase and quartz<sup>16</sup>, as well as finer amphibole embedded in phillipsite and smaller amounts of clear glass shards. The anorthoclase, previously dated by Peterson *et al.*<sup>14</sup>, gave an age of  $9.8 \times 10^6$  yr. The third nodule, Fan BD 20, is a slightly altered pumice fragment with about 6 mm of ferromanganese oxide coating. The pumice was crushed and the freshest fragments dated.

If the slow growth model of Goldberg and Arrhenius is assumed, average accumulations can be calculated from the potassium argon ages (Table 1), which are in good agreement with the slow rates of Goldberg<sup>7</sup>, Bender *et al.*<sup>8</sup>, and the <sup>230</sup>Th/<sup>232</sup>Th and the uranium disequilibrium methods presented here. The rates obtained by potassium argon are lower than those obtained by either the uranium

disequilibrium method or the <sup>230</sup>Th/<sup>232</sup>Th method. In only two cases can a direct comparison of methods be made. The 10 mm/10<sup>6</sup> yr rate determined by Goldberg using <sup>230</sup>Th/<sup>232</sup>Th on the "Horizon" nodule compares with the 2-3 mm/10<sup>6</sup> yr potassium argon rate. In DWHD 47 a rate of 0.5-1 mm/10<sup>6</sup> yr by potassium argon compares with the rate of 6 mm/10<sup>6</sup> yr determined by <sup>230</sup>Th/<sup>232</sup>Th on another nodule from the same dredge haul. The rates of accumulation range from 0.5 to 3.5 mm/10<sup>6</sup> yr by the potassium argon method, 6 to 18 mm/10<sup>6</sup> yr by the <sup>230</sup>Th/<sup>232</sup>Th method, and 24 to ~40 mm/10<sup>6</sup> yr by the <sup>234</sup>U/<sup>238</sup>U method. The agreement of the methods is good, especially considering the fact that the methods were applied to different nodules.

The potassium argon ages of the centres of the nodules dated indicate a very old age, and yet these nodules were recovered by surface dredging. These two facts invalidate the argument that very slow rates are impossible because nodules accumulating this slowly would be buried by the more rapid accumulation of pelagic sediments. This, taken with the fact that the systematic decay of <sup>230</sup>Th/<sup>232</sup>Th and <sup>234</sup>U/<sup>238</sup>U in the nodule indicates a continuous growth of the nodule, definitely supports a slow growth model.

This work was conducted under a contract between the University of California and the Division of Biology and Medicine, U.S. Atomic Energy Commission. J. R. D. was supported by a Kennecott Copper Corporation fellowship during this research. We thank E. D. Goldberg, W. S. Broecker and T. Ku, and E. Bonatti for critically reviewing this manuscript.

### Origin of Diagenetic Pyrite in the Quilon Limestone, Kerala, India

ALTHOUGH microscopic pyrite from marine and non-marine argillaceous sediments of most geological ages has been extensively studied, its mode of origin has not been clearly understood. Berner<sup>1</sup> and Kalliooski<sup>2</sup> attributed the origin to the reaction of hydrogen sulphide formed by sulphite reduction, with iron-bearing minerals in sediments; but these minerals were not discovered. I have recorded framboidal and other types of diagenetic pyrite in the thin bed of marine, fossiliferous, Quilon limestone<sup>3</sup> of Burdigalian age<sup>4</sup>. Recent examination of the heavy minerals from limestone samples at Padappakara the type area has brought forward some new evidence, which clearly establishes that the fine-grained pyrite was produced by an alteration of detrital, iron-bearing mica, optically identified as biotite.

The soluble part of the limestone was removed by digestion in concentrated hydrochloric acid. The insoluble residue, thoroughly cleaned and dried, was screened using 60, 100 and 200 mesh sieves. The heavy minerals were separated in bromoform and permanently mounted in Canada balsam. For microscopic examination reflected light and a high power magnification of  $\times 315$  were found to be satisfactory. Pyrite was abundant in all the slides irrespective of size. Among the different morphological types recognized were crystal aggregates, microfaunal infillings, pseudomorphs, framboids and their spherical aggregations and scattered idiomorphs. The last three types were restricted to the finer fractions, whereas the rest are almost equally common in all the sizes of fractions. Besides cubes, octahedra and pyritohedra<sup>5</sup>, previously reported by others in argillaceous sediments elsewhere, combinations of cubes and octahedra, with any one of the forms better developed than the other, and interpenetrating cubes, are also reported here for the first time.

The crystal aggregates are tabular or slab-like and made of closely packed euhedra. Microfaunal infillings are characteristically seen in the foraminifers where each chamber is filled with a cluster of tiny pyrite crystals. Some bivalved micro-organisms are represented by pseudomorphs, composed of dull, cryptocrystalline pyrite which may be epigenetic.

Many of the tabular slabs of crystal aggregates have some of their edges straight and smooth, whereas the others appear fractured, embayed or jagged due to unevenly projecting crystals. The jagged edges are partly covered by a translucent brown sheath of biotite, which is evidently a remnant of the parent mineral left after the formation of the enclosed pyrite. Some slabs are completely covered by the sheath, which releases the pyrite contents when the sample is disrupted. Love<sup>6</sup> mentioned sacs or pellicles of organic matter as forming an outer cover around the pyrite. In the case of the material investigated, however, the sheath undoubtedly consists of mica and no trace of any organic matter could be found.

The occurrence of biotite is less frequent in the heavy minerals than might be expected in view of its profusion in the Archaean crystalline rocks of the region. This is so because much of the originally present mica has disappeared by alteration to pyrite. Some of the tabular slabs still retain the original pseudo-hexagonal outline of the biotite.

Dust-like, opaque inclusions are common in the detrital biotite and are found to be pyrite. Some flakes show only a skeletal development of pyrite which may indicate abrupt environmental changes. The grains being sparsely distributed, such flakes enable the observation of genetic details of the pyrite. It can clearly be seen that the pyrite euhedra are formed in more than one generation. The crystals formed earlier are coarser, more widely spaced and are distributed in such a way as to simulate the intersections of a network. These serve as nuclei around which the finer crystals formed later closely adhere. Some of the nuclei seem to give rise to framboids, while others produced crystal aggregates. The geometrical pattern of the network strongly suggests that the atomic structure of the parent mineral influences the mode of development and distribution of the resulting pyrite.

The present investigation has further shown that all iron-bearing minerals are not prone to pyritization though they may be controlled by the same environmental conditions. For example, almandine, which is a major constituent of the heavy minerals, has not been altered in the least. Some ilmenite grains from the assemblage show a regular lamellar structure which results from deep, selective corrosion of alternate layers. The lamellae are thinly coated with pyrite, but this evidence does not conclusively prove its susceptibility to pyritization.

Pyrite is also found as inclusions in almandine and other heavy minerals of the assemblage such as silli-

manite, amphibole and hypersthene. The inclusions are generally in the form of cubes and octahedra, but occasionally framboids are also noted. These have apparently developed by pyritization of the original biotite inclusions in the host minerals. I am not aware of any previous record of a similar occurrence of pyrite as inclusions.

Framboids and morphologically related aggregations are generally regarded as resulting from the crystallization of iron sulphide gel. Whether the single crystals, occurring in between the framboids, as noted in the biotite under alteration, passed through a gel stage or were formed directly by the simple interaction between hydrogen sulphide and iron under favourable physical and chemical conditions is not known. The geometrical pattern of distribution of pyrite in the biotite tends to show that the interaction, including the precipitation of the gel, was restricted to certain points only as determined by the atomic structure of the biotite. The microfaunal infillings seem to represent an influx of extraneous gel which eventually crystallized within the chambers into tiny pyrite euhedra. The inclusions of single crystals and framboids of pyrite found in the associated heavy minerals of the assemblage were probably produced by hydrogen sulphide coming directly into contact with and interacting with the original biotite inclusions. Further work on the hydrogen sulphide susceptible structure of the mica and the mechanism of interaction is in progress.

I thank Mr. K. P. Thiruvikramaji for field and laboratory assistance.

## A New Radio-carbon Date for Wales

THIS communication presents the results of a radio-carbon age determination on organic material recently found in fluvioglacial deposits exposed in the workings of the Cardiganshire Sand and Gravel Co. at Banc-y-Warren (Cardiganshire), (SN 202482). This well developed kame-complex was described by Williams in 1927 (ref. 1).

The deposits, which have a minimum thickness of 150 ft., contain "Welsh" and "Irish Sea" erratics including Cambrian grits, Old Red Sandstone, flint, chalk and igneous rocks. Shell fragments are common throughout the succession. In the section examined, stratified sand up to 40 ft. thick was overlain unconformably by bedded gravels, pebbles and cobbles, passing upwards into more stratified sand to a total thickness of approximately 110 ft. The regional stratigraphic relationships were determined by Williams, who found that equivalent fluvioglacial deposits nearby directly overlie stiff blue "Lower Boulder Clay" at Llwyn-llwyd Farm and at Rhos-llyn. Some 70 ft. below the top of the section at Banc-y-Warren, within the gravel layer, a discontinuous horizon of peaty organic mud was found. Approximately 40 g of this was taken for radio-carbon analysis from a point 4 ft. behind the quarry face, which at the time was being actively worked. The sample has been dated by Isotopes Inc., New Jersey (Sample No. 1-2559), as  $31,800^{+1,400}_{-1,200}$  years B.P. The point from which the sample was taken makes it extremely unlikely that it has been contaminated by rainwater percolating downward.

Previous attempts to delimit the extent of the Würm glaciation in western Wales are summarized in Fig. 1, and demonstrate a considerable diversity of opinion. An early attempt was that of Lewis<sup>2</sup>, whose suggestion that the Irish Sea Ice did not cross the Llyn peninsula was rejected by Charlesworth<sup>3</sup>. The latter's "Newer Drift" limit in south-west Wales was in part based on the "conspicuous marginal accumulation" at Banc-y-Warren<sup>3</sup>. Synge regarded the deposit as eroded outwash of Riss (Saale) age<sup>4</sup>. Mitchell, in attempting a correlation between the Welsh and Irish Pleistocene chronologies, suggested that Irish Sea Ice did not impinge on the west coast of Wales during the Würm glaciation<sup>5</sup>. This suggestion has received additional support from Synge who considered that the Brynair moraine, in north-west Wales, marks the maximum extent of the Irish Sea Ice during the Würm<sup>6</sup> (see Fig. 1). By implication, any drifts to the south of Brynair are either pre-Würm in age, or are of a periglacial origin, most probably of Würm age, as proposed by Watson<sup>7</sup>. Shell fragments collected by B. S. John from glacial sands and gravels at Mullock Bridge (SM 811080) and Tre-llys (SM 898349) have previously been dated as  $37,960 \pm 1,700$  years B.P. and  $37,310 \pm 1,515$  years B.P. respectively, providing evidence for "an extensive glaciation of Western Britain later than 38,000 years B.P."<sup>8</sup>. The validity of these dates has been questioned by Bowen, who suggested that the shells may have been contaminated by downward percolating groundwater<sup>9</sup>. Bowen and Gregory did, however, accept the possibility that Weichselian (Würm) ice impinged on a small area in north Pembrokeshire and south Cardiganshire<sup>10</sup>.

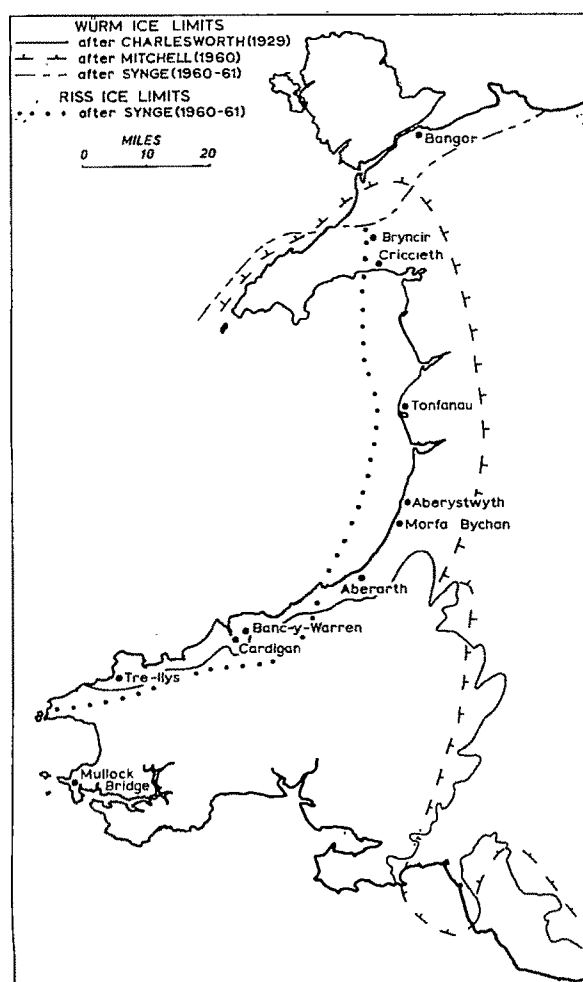

Fig. 1.

By comparison with the known European succession, Boulton and Worsley<sup>11</sup> suggest that a radio-carbon date of  $28,000 \pm 1,800$  years B.P. obtained from shells in fluvio-glacial material at Sandiway (SJ 605708), north of the Ellesmere moraine on the Cheshire-Shropshire plain, indicates a glaciation of Late-Weichselian age, post-dating the Paudorf interstadial (30,000 to 25,000 years B.P.). The date here given for Banc-y-Warren (31,800 years B.P.) would on this basis appear to pre-date the Paudorf interstadial and might therefore be correlated with the "Advance Phase"<sup>12</sup> of the Main Würm of the continental succession.

The Brynair moraine can no longer be considered to mark the southern limit of Würm ice on the eastern flank of the Irish Sea basin, but perhaps it may represent a pause in the recession of that ice-sheet. Alternatively, the Brynair moraine could be the product of a re-advance which post-dates the Paudorf interstadial and hence, on the basis of the shell dates obtained by Boulton and Worsley<sup>11</sup> from Sandiway, be correlated with the Ellesmere moraine.

The presence of numerous north Welsh erratics within the fluvio-glacial deposits at Banc-y-Warren is almost certainly indicative of the contemporaneous existence of Welsh ice.

The age determined for Banc-y-Warren supports John's concept of an extensive Würm glaciation in the Irish Sea basin<sup>8</sup> the limits of which lay well to the south of those proposed by either Mitchell<sup>5</sup> or Synge<sup>6</sup>.

We thank Professor E. H. Brown for help and encouragement; the Department of Geography, University College of London, for financial assistance; Miss V. Pearce, who drew the map; and the proprietors of the Cardiganshire Sand and Gravel Co. for permission to work in their quarry.

## THE SOLID STATE

### Determination of the Cation Distribution in the Orthopyroxene Series by the Mossbauer Effect

MEASUREMENTS of the distribution of cations and the detection of order-disorder phenomena in crystal structures provide a potential means of determining the temperature and pressure of formation of minerals. Such data have been obtained from crystal structure analyses of iron silicates by X-ray diffraction techniques (refs. 1-7 and Gibbs, G. V., and Burnham, C. W., personal communications). More rapid and direct techniques, such as infra-red spectroscopy<sup>8</sup> and Mossbauer spectroscopy<sup>9,10</sup>, have since been used to detect cation ordering and to estimate site populations in suites of silicate minerals.

We have used Mossbauer spectroscopy to estimate site populations in a suite of orthopyroxenes derived from regionally metamorphosed rocks<sup>11</sup>. Measurements were made at room temperature<sup>9,12</sup> on five orthopyroxenes of the enstatite–orthoferrosilite series with 14.5–85.9 cation per cent iron (II), and a manganiferous orthopyroxene with 74.8 per cent iron (II) and 9.2 per cent manganese (II). (Fe(II) and Mn(II) refer to the high spin divalent species.) All spectra were obtained using a stainless-steel source; however, duplicate spectra of the 85.9 per cent iron (II) and manganese orthopyroxenes were run with a palladium source and gave better resolution and decreased statistical errors.

Computer plots of three orthopyroxene spectra are shown in Fig. 1. Specimens exceeding 23.1 per cent iron (II) were fitted by computer to four Lorentzian curves, and all parameters were allowed to vary independently. Only the inner two peaks were resolved in the spectra of the 14.5 and 23.1 per cent iron (II) orthopyroxenes, but the widths of these peaks were slightly larger than those of the resolved peaks in the spectra of orthopyroxenes rich in iron. Computer-calculated areas under the peaks are summarized in Table 1, together with standard deviations.  $A_1$  and  $A_2$  refer to the sum of the areas of the outer two and inner two peaks, respectively.

The orthopyroxene structure<sup>4,13</sup> contains two positions of six-fold co-ordination which are designated  $M_1$  and  $M_2$ . Cations in the  $M_1$  positions are co-ordinated to six oxygen ions each linked to one silicon atom. Cations in the  $M_2$  positions are surrounded by four oxygen ions each linked to one silicon atom, and two bridging oxygen atoms which are each shared by two silicon atoms. The octahedron about the  $M_1$  position has a symmetry which is approximately octahedral, but the oxygen polyhedron about the  $M_2$  position is considerably distorted from octahedral symmetry. Average metal–oxygen distances in the two sites in hypersthene<sup>4</sup> are:  $M_1$  site, 2.092 Å;  $M_2$  site, 2.220 Å. Thus, the orthopyroxene  $M_1$  and  $M_2$  sites differ significantly, both geometrically and energetically.

The resolved peaks in the Mossbauer spectra of orthopyroxenes can be assigned as follows: inner two peaks to iron (II) in the  $M_2$  position, outer two peaks to iron (II) in the  $M_1$  position. X-ray diffraction measurements<sup>4</sup> of a 50.0 per cent iron (II) orthopyroxene indicated that iron occurs predominantly in the  $M_2$  position. This may be

correlated with the Mossbauer spectrum of the 48.4 per cent iron (II) orthopyroxene (Fig. 1b), which shows the inner two peaks to be the more intense. Furthermore, the smaller quadrupole splitting of the inner peaks<sup>14</sup> conforms with the occurrence of iron (II) ions in the more distorted co-ordination site<sup>15</sup>.

The proportions of iron in the  $M_2$  and  $M_1$  positions,  $n_2/n_1$ , can be obtained from the ratio  $A_2/A_1$  of the computer calculated peak areas (Table 1) using the relationship

$$A_2/A_1 = C.n_2/n_1.$$

The constant  $C$  can be evaluated precisely from the spectrum of orthoferrosilite ( $\text{Fe}_2\text{Si}_2\text{O}_6$ ). Because synthetic<sup>16</sup>  $\text{Fe}_2\text{Si}_2\text{O}_6$  was not available to us, and naturally occurring orthopyroxenes exceeding 85.9 per cent iron (II) are unknown, we have estimated the constant  $C$  to be 0.90 (ref. 9). For a 35.4 per cent iron (II) cummingtonite, this value of  $C$  gives site populations which are in excellent agreement with those obtained by X-ray diffraction<sup>7</sup>. Because there is close structural similarity between the orthopyroxene  $M_2$  and cummingtonite  $M_4$  sites, and between the orthopyroxene  $M_1$  and cummingtonite  $M_3$ ,  $M_2$  and  $M_3$  sites, a value of  $C$  similar to that chosen for the cummingtonite–grunerite series appears to be reasonable for the orthopyroxene series. Site populations calculated from values of  $C$  of 0.85, 0.90 and 0.95 are summarized in Table 1.

The results summarized in Table 1 show that calculated site populations are relatively insensitive to changes in the constant  $C$ . The quantitative site populations estimated from the Mossbauer spectra show that iron (II) ions are concentrated in the  $M_2$  position of the orthopyroxene structure, and that manganese is enriched more strongly than iron in the  $M_2$  position. The manganese–iron ordering can be gauged from the data for the 85.9 per cent iron (II) and manganiferous orthopyroxenes, which have almost identical contents of iron (II) + manganese (II) + calcium (II), and the 72.7 per cent iron (II) and manganiferous orthopyroxenes (similar content of iron (II)).

Similar results for manganese–iron ordering were obtained by X-ray diffraction<sup>4</sup>. Ghose<sup>4</sup> used a granulite facies hypersthene with 1.00 iron (II), 0.01 manganese (II) and 0.05 calcium (II) per formula unit, and estimated that the  $M_2$  position contained 90 per cent iron (II) and the  $M_1$  position 15 per cent iron (II). The results can be

Fig. 1. Computer plots of the Mossbauer spectra of minerals of the orthopyroxene series. a, 23.1 per cent iron (II); b, 48.4 per cent iron (II); c, 85.9 per cent iron (II).

Table 1. DISTRIBUTION OF IRON (II) IONS IN ORTHOPYROXENES FROM MOSSBAUER SPECTROSCOPY

Specimen	Iron (II) (per cent)	Iron (II) per formula unit	Manganese (II) per formula unit	Calcium (II) per formula unit	$\Delta_2$ counts $\times$ channels $\times 10^{-5}$	$\Delta_1$ counts $\times$ channels $\times 10^{-5}$	Iron (II) in $M_1$ and $M_2$ position					
							$C=0.85$ $n_2$	$C=0.85$ $n_1$	$C=0.90$ $n_2$	$C=0.90$ $n_1$	$C=0.95$ $n_2$	$C=0.95$ $n_1$
Bamle Norway	14.5	0.29	0.01	0.01	3.55 $\pm 0.10$	not resolved	$n_2 \geq$		0.27	$n_1 \leq$	0.03	
Howie	23.1	0.46	0.01	0	4.52 $\pm 0.12$	not resolved	$n_2 \geq$		0.43	$n_1 \leq$	0.04	
Howie 68971	48.4	0.97	0.02	0.05	4.24 $\pm 0.35$	1.65 $\pm 0.33$	0.73	0.24	0.72	0.25	0.71	0.26
Howie	72.7	1.45	0	0.04	3.63 $\pm 0.25$	3.41 $\pm 0.25$	0.81	0.64	0.79	0.66	0.77	0.68
Kuno K23	85.9	1.72	0.01	0.04	5.58 $\pm 0.15$	5.81 $\pm 0.15$	0.91	0.81	0.89	0.83	0.86	0.86
Henry Cambridge 190553	74.8 (9.2 per cent manga- nese (II))	1.50	0.18	0.07	6.50 $\pm 0.14$ 8.28 $\pm 0.12$	10.04 $\pm 0.15$ 4.30 $\pm 0.12$	0.65	0.85	0.63	0.87	0.60	0.90
							0.71	0.79	0.69	0.81	0.67	0.83

compared with those obtained in the present investigation for a charnockitic hypersthene with 48.4 per cent iron (II) (0.97 iron (II), 0.02 manganese (II) and 0.05 calcium (II) per formula unit), which indicate that about 72 per cent and 25 per cent of the  $M_2$  and  $M_1$  positions, respectively, are occupied by iron.

Because the quadrupole splitting of the two doublets approaches a similar value at low iron concentrations<sup>14</sup>, resolution of the outer doublet is impossible in the 14.5 per cent and 23.1 per cent iron (II) orthopyroxenes, and statistical errors are rather large in the 72.7 per cent and 48.4 per cent iron (II) orthopyroxenes (> 15 per cent). In the cummingtonite-grunerite and anthophyllite series, the statistical errors were considerably smaller<sup>9,10</sup>. Statistically acceptable  $\chi^2$  (less than 400 for a 400 point spectra) were obtained for the 14.5 per cent, 48.4 per cent and 85.9 per cent iron (II) samples. Higher values for the other three samples suggests that there are very small contributions to the spectra from other iron atoms (for example, iron (III), or iron (II) in the  $M_1$  position in the 23.1 per cent iron (II) orthopyroxene).

We thank Dr. S. O. Agrell, Dr. N. F. M. Henry and Dr. H. Kuno for mineral specimens. G. M. B. acknowledges a Shell postgraduate scholarship, and R. G. B. thanks the Science Research Council for a grant.

## PHYSICS

### Thin Silicon Solar Cells for Large Flexible Arrays

THE past year has witnessed increasing interest in solar-powered, electrical propulsion systems for spacecraft in both the United States and the United Kingdom. In the United States the main interest is in the use of electrical propulsion for missions to Mars and Jupiter, where there is a marked payload advantage over chemically powered spacecraft which are limited by their energy rather than by their power. The incentive for the United Kingdom to initiate development in this field was provided by Burt<sup>1</sup> who theoretically showed that it was possible to change independently all the elements of a spacecraft's orbit by means of small continuous thrusts from an electrical propulsion unit. In particular, he showed that the ability of the unit to change the inclination of an orbit made it possible for a communications satellite launched from a non-equatorial site to attain a geostationary orbit.

The power required for such a mission would be from 1 to 2 kW, and this would give a tangential acceleration of about 0.1 cm sec<sup>-2</sup>. With this acceleration, it would be possible to climb from a circular orbit of 550 km to a synchronous altitude in about 50 days.

Silicon solar cells offer a promising approach to the problem of providing kilowatts of power over periods of several years on account of their reliability, adaptability and advanced technological status. The most important requirements for large arrays are low specific mass—20 kg kW<sup>-1</sup> for the mission already mentioned—and the ability to stow and to support the assembly in a small volume for launching.

Specific mass can, of course, be reduced by improving the conversion efficiency obtained by expressing the maximum cell output power as a percentage of the input power (that is, the mean solar irradiation above the Earth's atmosphere multiplied by the active cell area) and which at present stands at about 11 per cent for an *n-on-p* cell at 300° K. The theoretical limit for a planar *p-n* junction at this temperature (assuming that 10<sup>-3</sup> recombinations of electron-hole pairs are radiative) is 22 per cent, so an increase to the theoretical maximum performance would halve the specific mass of an array and, with it, the specific area. From past experience, actual achievements in this direction during the next few years are likely to be marginal.

A much more significant saving can be made by using a thin plastic substrate instead of the conventional rigid support and reducing the thickness of the solar cells. Such assemblies are sufficiently flexible to permit large areas to be wrapped around the body of a spacecraft or around a separate drum, and thus meet the requirement for stowage and support during launch. A reduction in the thickness of the cell from 400 to 100  $\mu$  has already been achieved in pilot production.

Fig. 1. Short-circuit current of 100–400 $\mu$  silicon solar cells irradiated with electrons.

Fig. 2. Power output of 100–400 $\mu$  silicon solar cells irradiated with electrons.

Silicon cells cannot be thinned to this extent without some loss of response to red and infra-red light (Fig. 1, insert). Because of the predominance of indirect transitions in silicon, photons in the red and infra-red wave bands are absorbed at an appreciable depth. For example, at a wavelength of  $1\mu$  the absorption coefficient is  $100\text{ cm}^{-1}$  and this gives a depth of penetration of  $100\mu$ . In order that the photo-generated minority carriers (electrons in the case of a  $p$ -type base region) at this depth can contribute to the output of the cell, a long diffusion length is necessary for minority carriers. The diffusion length  $L$ , or mean distance moved by an electron or hole during its lifetime, determines the effective thickness of the cell. In thin cells, there is an additional loss because of the proximity of the rear contact which covers most or all of the back surface of the cell and facilitates a very high surface recombination rate for minority carriers.

Wolf and Ralph<sup>2</sup> have computed the variation of short circuit current as a function of the thickness of a solar cell. They found that at thicknesses of cells of less than  $300\mu$  the measured short circuit currents inexplicably decreased at twice the rate of the theoretical curves.

The results of our experiments on 100–400 $\mu$  shallow junction,  $10\Omega\text{ cm } n\text{-on-}p$  silicon cells are shown in Figs. 1

and 2. The good agreement with theory (Fig. 1) has been achieved, we believe, by accurate measurement and the elimination of work damage at the rear silicon surface during fabrication of the cell. Estimates of the specific mass of flexible arrays show that the poorer initial performance of the  $100\mu$  cell is more than counter-balanced by its smaller mass when compared with cells of conventional thickness.

Another interesting feature of thin silicon cells is their radiation resistance. Electron or proton irradiation produces lattice defects in the crystal which behave intrinsically, or in combination, with other impurities as recombination centres, reducing the diffusion length of minority carriers according to the relation

$$L^{-2} = L_0^{-2} + K\Phi$$

where  $L_0$  is the initial value of the diffusion length,  $L$  the value after an integrated flux  $\Phi$  and  $K$  the damage coefficient.

The degradation of diffusion length reduces the effective thickness of a conventional cell and results in a reduction in the response to red and infra-red light similar to that caused by physically thinning the cell.

Investigations of radiation damage carried out at the Royal Aircraft Establishment have shown that, after a flux of  $10^{15}$  electrons  $\text{cm}^{-2}$  at 1 MeV, the spectral responses (Fig. 1) and consequently the performance (Fig. 2) of 100 and  $400\mu$  cells are very nearly the same. The performance degradation after  $10^{15}$  electrons  $\text{cm}^{-2}$  corresponds to a reduction of the diffusion length of minority carriers from an initial value of  $160\mu$  to  $30\mu$ . The damage coefficient  $K$  is  $8.89 \times 10^{-11}$  electrons $^{-1}$ . Recent experiments with 70–140 MeV protons have shown a similar effect.

The superior radiation resistance of thin cells will be of particular value when a spacecraft has to traverse the Van Allen proton belt. The recent work by R.C.A. towards the development of a lithium doped  $p\text{-on-}n$  silicon cell resistant to radiation<sup>3</sup> promises a further bonus in this context.

## CHEMISTRY

### Some Electrical Properties of Bimolecular Phosphatidyl Inositol Membranes

THE formation of "black", bimolecular lipid membranes in aqueous solutions was first reported by Mueller *et al.*<sup>1</sup> in 1962 and has since been investigated by several research groups<sup>2-7</sup>. Most of the work has been carried out with phosphatidyl choline (lecithin) from natural sources, although "black" films could also be obtained with diglycerides<sup>5</sup>, sphingomyelin<sup>7</sup> and synthetic dioleoyl phosphatidyl choline<sup>7</sup>. A common property of all these com-

pounds is that the net charge of the molecule is zero. It is of interest that several types of negatively charged lipids, for example, phosphatidyl serine or phosphatidyl inositol, are found in cell membranes. Because of speculations on the biological functions of these lipids<sup>8</sup> it was of interest to investigate the electrical properties of artificial bimolecular membranes bearing negatively charged groups.

"Black" membranes were obtained from a 0.5 per cent (w/v) solution of phosphatidyl inositol in *n*-decane. The membranes were formed at 35° C on a circular aperture in the wall of a 'Teflon' cell which was immersed in an aqueous salt solution<sup>7</sup>. With salt concentrations of  $c \geq 10^{-3}$  moles/l. the membranes were stable for several hours. The phosphatidyl inositol was purchased from Sigma (grade II, from bovine brain) and further purified on a DEAE cellulose column<sup>9</sup>.

The electrical capacitance of membranes of phosphatidyl inositol was found to be  $0.29 \pm 0.03 \mu\text{F}/\text{cm}^2$ , which is slightly lower than the value observed with membranes of phosphatidyl choline<sup>3,7</sup>. Using the same assumptions as in ref. 7, a thickness of 80 Å is calculated for the membrane of phosphatidyl inositol.

In solutions of potassium chloride the electrical resistance of these membranes is very high and almost independent of the salt concentration—the values for individual membranes varied between  $5 \times 10^7$  and  $5 \times 10^8 \Omega \text{ cm}^2$ . Resistances of the same order of magnitude were observed with phosphatidyl choline membranes in potassium chloride solutions<sup>3,7</sup>. It seems that only the highest resistance values are true resistances of the black film, and that the lower values result from border leakages<sup>10</sup>. By replacing the chloride ions in the solution by iodide ions it was possible to reduce the resistance of the phosphatidyl choline membrane by a factor of about one thousand<sup>7</sup> and to demonstrate that the membrane resistance in iodide solutions is a true property of the black film<sup>7</sup>. With phosphatidyl inositol membranes the effect of the iodide ions on their resistance was much lower but could be greatly enhanced when a large excess of an "indifferent" salt, such as potassium chloride, was added. This can be seen in Table 1 in which the resistances of a phosphatidyl inositol membrane at 35° C are summarized. The observed resistance values vary from membrane to membrane. The effect of the iodide ion on the resistance of a membrane is always reversible: if the ( $10^{-2}$  molar potassium iodide + 2 molar potassium chloride) solution was replaced by 2 molar potassium chloride at the end of the experiment, the membrane resistance returned to a very high value.

In a further series of experiments the electrical resistance of membranes prepared from mixtures of phosphatidyl choline and phosphatidyl inositol was investigated (compare Fig. 1). When the composition of the solution was gradually changed from pure phosphatidyl choline in *n*-decane to pure phosphatidyl inositol in *n*-decane, the membrane resistance increased by a factor of about 300 from  $0.049 \times 10^6$  to  $16 \times 10^6 \Omega \text{ cm}^2$ . It is emphasized, however, that the molar ratio in the black film is not necessarily the same as in the decane solution.

The interesting observation that the resistance of a phosphatidyl inositol membrane in  $10^{-2}$  molar potassium iodide can be reduced by a factor of about one hundred by adding a large excess of potassium chloride even though the resistance in a solution of potassium chloride alone is very high can be explained by the fact that the surfaces of the membrane are ionized. If the area occupied by a molecule of phosphatidyl inositol in the membrane is assumed to be  $A \approx 40 \text{ Å}^2$  (a value suggested by monolayer investigations<sup>11</sup>) and if each molecule is ionized, then the surface charge density of the membrane is  $q = -e_0/A \approx$

Fig. 1. Electrical resistance of mixed phosphatidyl choline/phosphatidyl inositol membranes in  $10^{-2}$  molar potassium iodide as a function of the composition. PC and PI are the concentrations (mg/ml.) of phosphatidyl choline and phosphatidyl inositol, respectively, in the solution from which the membrane was formed.

$-4.0 \times 10^{-5}$  coulomb/ $\text{cm}^2$  ( $e_0$  is the elementary charge). The negative charge of the membrane is electrically neutralized by a diffuse layer of opposite charges in the solution. From the theory of the diffuse double layer<sup>12</sup> the following relation between the charge density  $q$  and the electrical potential  $\phi_s$  at the surface of the membrane is derived (for a 1 : 1 electrolyte solution):

$$q = \sqrt{\left(\frac{2}{\pi} \epsilon c RT\right)} \sinh\left(\frac{\phi_s F}{2RT}\right) \quad (1)$$

Here  $\epsilon$  is the dielectric constant of water,  $c$  is the total salt concentration,  $R$  is the gas constant,  $T$  is the absolute temperature, and  $F$  is the Faraday constant. This equation should be considered as only approximate. In more concentrated electrolyte solutions a part of the membrane charge may be screened by a layer of closely associated ions of opposite charge (the "Helmholtz layer"). In this case  $q$  should be replaced by an effective charge density  $q_{\text{eff}}$  with  $|q_{\text{eff}}| < |q|$ ;  $\phi_s$  is then the potential at the outside of the Helmholtz layer. For the sake of simplicity we assume  $q_{\text{eff}}$  to be independent of the concentration of the electrolyte. Previously, it was found that the membrane conductivity in iodide solutions is a function of the concentration of the iodide ions and independent of the cation<sup>7</sup>. It is therefore feasible to describe the membrane conductivity by the following equation

$$\frac{1}{R_m} = \text{constant} \times (c_1)_s \quad (2)$$

where  $R_m$  is the resistance of  $1 \text{ cm}^2$  of the membrane and  $(c_1)_s$  is the concentration of the iodide ions at the membrane surface. Because the electrical potential  $\phi_s$  at the membrane surface is negative with respect to the solution, the concentration  $(c_1)_s$  is smaller than the concentration of the iodide ions  $(c_1)_0$  in the bulk solution by the Boltzmann factor  $\exp(\phi_s F/RT)$

$$(c_1)_s = (c_1)_0 \exp(\phi_s F/RT) \quad (3)$$

so that equation (2) assumes the form

$$R_m = R_0 \exp(\phi_s F/RT) \quad (4)$$

Substitution of  $\phi_s$  from equation (1) leads to

$$R_m = \frac{\alpha R_0}{1 + \alpha - \sqrt{1 + 2\alpha}} \quad (5)$$

$$\alpha \equiv \frac{\epsilon c RT}{\pi q^2} \quad (6)$$

For small values of  $\alpha$ , equation (5) can be replaced by the approximation

Table 1. ELECTRICAL RESISTANCE OF AN INDIVIDUAL PHOSPHATIDYL INOSITOL MEMBRANE IN DIFFERENT ELECTROLYTE SOLUTIONS

2 molar KCl	$1.1 \times 10^8 \Omega \text{ cm}^2$
$10^{-2}$ molar KI	$1.9 \times 10^7 \Omega \text{ cm}^2$
$10^{-2}$ molar KI + 2 molar KCl	$1.5 \times 10^6 \Omega \text{ cm}^2$

$$R_m \approx \frac{2R_0}{\alpha} \quad (5a)$$

With  $q = -4 \times 10^{-6}$  coulomb/cm<sup>2</sup>,  $\alpha = 0.091$  for an aqueous solution of  $c = 2$  moles/l. The approximation (5a) is therefore valid for the whole range of concentrations. If the membrane resistance were measured in two solutions with identical values of  $(c_1)_0$  but different total concentrations  $c_1$  and  $c_2$ , according to equations (5a) and (6) the resistance ratio would be expected to be

$$\frac{R_m(c_1)}{R_m(c_2)} = \frac{c_2}{c_1}$$

In our experiments with  $c_1 = (c_1)_0 = 10^{-3}$  moles/l. and  $c_2 \approx 2$  moles/l., a resistance ratio of 130 was found which agrees approximately with the calculated ratio of 200. It can therefore be concluded that the influence of an added indifferent electrolyte on the iodide conductivity of the membrane can be explained by an electrostatic double layer effect.

### Pairwise Trapping in Solid State Photo-eliminations

UNDER certain circumstances radicals may be trapped in pairs which are so well separated that there is no chemical bond between them, but sufficiently close that there is a magnetic coupling between the unpaired electrons. If the trapping is sufficiently precise this may be revealed in the electron spin resonance spectrum which will be characteristic of a triplet-state species<sup>1,2</sup>.

Photolyses or radiolyses sometimes involve the elimination of small stable molecules such as nitrogen or carbon monoxide, and if this occurs in a rigid medium the resulting radicals would seem to be ideally placed for the production of such weakly coupled systems with the precision required for detection. We have recently established that  $\gamma$ -irradiation of crystalline diaryl carbonates, which involves formation of carbon monoxide, gives pairs of aryloxy radicals separated "magnetically" by about 6 Å (ref. 3). The purpose of the present communication is to call attention to the solid state ultra-violet photolysis of azobisisobutyronitrile, which results in a species with an electron spin resonance spectrum which is also characteristic of a triplet.

The reaction was originally written as (1) (ref. 4),

(2)

rather than (2), but the spectrum has exactly the form required for radical-pairs (Fig. 2 of ref. 4). The separation of about 280 G between the outer features corresponds

to an effective or "magnetic" separation between the radicals of 5.8 Å which is very close to expectation if the two  $(\text{CH}_3)_2\text{CCN}$  radicals simply become planar on the extrusion of a nitrogen molecule. The hyperfine coupling, which is probably dominated by the methyl group protons, is about half that assigned to the protons in separated  $(\text{CH}_3)_2\text{CCN}$  radicals<sup>4</sup> as would be expected for pairs undergoing rapid spin exchange<sup>5</sup>.

This result is of considerable importance because it proves that nitrogen is either extruded in a one-step process or, less reasonably, that the radical  $\text{N}_2\text{C}(\text{CH}_3)_2\text{CN}$  loses nitrogen spontaneously even at 77° K.

The alternative interpretation<sup>4</sup> that a single radical,  $\text{N} = \text{NC}(\text{CH}_3)_2\text{CN}$ , was responsible for the spectrum is improbable because this radical is expected to be bent at the inner nitrogen atom, with the unpaired electron in a  $\sigma$ -orbital<sup>6</sup>. This is expected to give a spectrum quite different from that detected.

### Voltages produced by Oxygen in Platinum-Sodium Chloride Crystal Cells

IT has been found that single crystals of sodium chloride annealed in nitrogen under mild compression between platinum electrodes produce electrical potentials when treated with traces of oxygen at 700°–730° C.

Specimens cleaved to blocks 10 × 10 × 3 mm were placed with the two large surfaces in contact with flat platinum electrodes which rested against recrystallized alumina disks for electrical insulation. The assembly was slightly compressed by springs adjusted to finger tightness. The crystal holder and silica cell were essentially the same as those described in detail by Allnatt and Jacobs<sup>1,2</sup>. The cell was evacuated to a pressure of 10<sup>-6</sup> mm of mercury overnight at room temperature and filled with "pure" nitrogen gas (10 p.p.m. of oxygen according to the manufacturer) which had been passed over hot copper turnings. All gases entered the cell through a methanol-solid carbon dioxide trap. The gas flow rates in the experiments mentioned here were all approximately 20 ml./min. When the temperature was initially raised above 500° C a variable voltage of several millivolts was observed similar to that described for

Fig. 1. Voltage-time relation after entry of first portion of oxygen at A. Results are independent of absence or presence of the small thermoelectric voltage at  $t = 0$  in the graph.

Fig. 2. Voltage-time relation for oxygen treatments described in text.

potassium chloride and other crystals<sup>2</sup>. This vanished after annealing at 750° C for 1 h and various thermoelectric and a.c. conductivity measurements were made over a period of several days. Comparison of conductivity with values in the literature showed that the initial annealing perfected the electrode contact. The "knee" of the conductivity curve<sup>3</sup> was below 450° C. The potential between the electrodes as a function of time was next measured using an electrometer and a recorder.

In one run 50 ml. portions of 0.5 per cent oxygen in nitrogen were flushed through the cell with "pure" nitrogen. The first two portions, separated by 1 h, produced similar voltage oscillations after 5 and 6 min respectively (Fig. 1). A third portion of gas 25 min after the second produced no effect in 5 h. A series of experiments showed that the sensitivity to further gas samples was restored by annealing for periods of 1–12 h at the same temperature (700° C) or higher. The amplitude of voltage oscillations varied between 10 and 100 mV with four or five reversals of sign often occurring.

Fig. 2 summarizes another experiment at 730° C on a different specimen. Between A and B a stream of nitrogen not purified over hot copper was passed. The oxygen content was too small to produce an effect in 200 min. From B to C 0.5 per cent oxygen in nitrogen was passed and the usual voltage oscillations appeared after 50 min. From C to D a static atmosphere of the same gas was maintained; from D to E purified nitrogen was passed. Note the 140 mV peak, the relative slowness of its production and decay, and the absence of rapid oscillations. Crystals treated with several gas samples produced similar peaks in overnight anneals, but the peak voltages were only 10–20 mV, presumably because of the smaller amounts of oxygen passed.

Similar results to those shown in Figs. 1 and 2 were obtained for a crystal in which the surfaces in contact with platinum had been coated with graphite, and for a crystal containing  $2.3 \times 10^{-4}$  mole fraction of strontium chloride. The main features recur in each experiment, but the details are not very reproducible. For example, the voltage oscillation after the first gas portion in an experiment appeared from 5–50 min after first admission of gas.

Voltages can be produced by plastic deformation of alkali halide crystals because of the motion of charged dislocations<sup>4</sup>, but detailed studies have all been carried out near room temperature. The plasticity of such crystals near the melting point is also familiar and the method of perfecting the electrode contact already described, and used by other workers<sup>5</sup>, depends on this. Changes of thickness of up to 1 per cent occur. Embrittlement of sodium chloride by oxygen gas at room temperature is also well known<sup>6</sup> and may occur because gas atoms at the surface, or diffused into the surface layers, impede the motion of dislocations. The initial rapid voltage fluctuations are presumably connected with the flow of

dislocations during the early stages of embrittlement by oxygen in the surface layers and the variability in details from experiment to experiment is connected with slight differences in the amount and uniformity of compression inevitable in such a simple cell. By contrast the broad peaks, like that between D and E in Fig. 2, are formed after oxygen has had time to diffuse into the bulk of the crystal, presumably in the form of  $O_2^-$  ions observed by paramagnetic resonance<sup>6</sup>. This, together with the relative slowness of the voltage production, suggests a different but related process. Speculation on the details of the processes involved is of little use without experiments with more sophisticated apparatus designed for the study of mechanical properties at high temperatures.

### Study of Electronically Excited Iodine Atoms $I(5^2P_{1/2})$ by Time Resolved Emission

Donovan and Husain<sup>1-7</sup> have recently carried out a number of investigations on electronically excited iodine and bromine atoms,  $I(5^2P_{1/2})$  and  $Br(4^2P_{1/2})$ , by kinetic spectroscopy in absorption in the vacuum ultra-violet after flash photolysis of a number of gaseous halides. The long mean radiative life-times of these excited atoms<sup>8</sup> arising out of the electric dipole forbidden transitions to the ground states,  $I(5^2P_{3/2})$  and  $Br(4^2P_{3/2})$ , have facilitated such studies in absorption. This communication describes the study of the time resolved emission  $I(5^2P_{1/2}) \rightarrow I(5^2P_{3/2}) + h\nu$  ( $1.315\mu$ ) following the flash photolysis of gaseous trifluoroiodomethane ( $CF_3I$ ), monitored by means of a lead sulphide photoconductive cell placed at the exit slit of a high aperture grating monochromator (Bausch and Lomb,  $f$  4.4) and displayed on the screen of an oscilloscope. The concentrations of excited iodine atoms produced on photolysis<sup>2</sup> are sufficiently high to overcome the low value of the Einstein coefficient for spontaneous emission, and adequate intensities are thus obtained. A typical trace for the decay of the emission is shown in Fig. 1. The decay is slower for increasing pressures of argon in accordance with a process primarily controlled by diffusion to the walls of the reaction vessel<sup>2-4</sup>.

The rate of decay of  $I(5^2P_{1/2})$  outside the region of photolytic initiation can be written

$$-d[I(5^2P_{1/2})]/dt = (\Sigma k_i[M_i] + \beta'/p + A_{nm})[I(5^2P_{1/2})]$$

where  $\Sigma k_i[M_i]$  is the sum of the first order collisional deactivation rate coefficients by species  $M_i$ ,  $\beta'$  is the part of the rate coefficient for diffusion to the walls of the reaction vessel independent of pressure ( $p$ ), and  $A_{nm}$  is the Einstein coefficient for spontaneous emission. The term in induced emission is not included because, although a population inversion is readily observed in this system<sup>2</sup>, this is in the absence of laser action because these experiments do not make use of a laser cavity. The intensity of the emission detected ( $I$ ) is given by

$$I = \phi A_{nm}[I(5^2P_{1/2})]_t \\ = \phi A_{nm}[I(5^2P_{1/2})]_{t=0} \exp(-(\Sigma k_i[M_i] + \beta'/p + A_{nm})t)$$

using the rate equation.  $\phi$  is the fraction of the emitted light detected. Thus the slope of the semilogarithmic plot of the intensity against time yields the overall first order decay coefficient ( $k$ ) for the rate equation. These plots are linear over a range of the order of milliseconds and eventually depart from linearity due to rapid quenching by  $I_2$  formed by atomic recombination. The plot of  $k$  against  $1/p$  is, in turn, of slope  $\beta'$  and intercept  $A_{nm} + k_{CF,I}[CF_3I]$  for a trifluoroiodomethane/argon mixture. This is shown in Fig. 2 for mixtures containing trifluoroiodomethane at a pressure of 1 mm of mercury. The decay rates at the different pressures of argon are corrected for quenching by oxygen present as a trace impurity at a concentration of 0.4 p.p.m. using the value obtained by Donovan and Husain for deactivation by this molecule<sup>4</sup>. The measurement of small differences in decay rates due to small differences in diffusion rates at these relatively high pressures of argon, necessary to prevent a significant temperature rise on flashing, involves relatively large errors. We consider the form of Fig. 2 to be a satisfactory confirmation of the mechanism of the decay of  $I(5^2P_{1/2})$  described by the rate equation given here. Any possible contribution from collisionally induced emission could not readily be detected with the present experimental arrangement. This effect would be observed primarily in the magnitude of the intercept for the semilogarithmic plot of the emission intensity against time; the main contribution from such an effect to the slope would be included in the overall value of  $k$ . The plots of  $k$  against  $1/p$  were made for mixtures using different pressures of trifluoroiodomethane (0.5 mm, 2.0 mm and 10 mm (441 J)). The value for  $k_{CF,I}$  taken from the intercept for  $p_{CF,I} = 10$  mm of mercury, and attributed solely to collisional deactivation of  $I(5^2P_{1/2})$  by this molecule as the contribution by  $A_{nm}$  is relatively small, was found to be  $3.5 \pm 0.6 \times 10^{-16}$  c.c./molecule/sec, in accordance with a previous estimate of this quantity from vacuum ultraviolet measurements<sup>2,4</sup>. There was limited reproducibility in the slopes  $\beta'$  which should be equal, and the error in estimating  $A_{nm}$  from the intercepts ( $1/p = 0$ ) is large as the spontaneous emission coefficient is the small remainder of the sum of faster kinetic processes. The magnitude of  $\beta'$  combined with the solution of the diffusion equation for a cylinder<sup>9</sup> leads to a value for the diffusion

Fig. 2. First order decay coefficient ( $k$ ) for the emission from  $I(5^2P_{1/2})$  as a function of pressure of argon.  $p_{CF,I}$ , 1.0 mm; energy, 1,767 joules. O,  $k$  observed; ●,  $k$  corrected for quenching by 0.4 p.p.m. of oxygen in argon after ref. 4.

coefficient of  $I(5^2P_{1/2})$  in 1 atm. of argon of  $0.41 \pm 0.05$  cm<sup>2</sup> sec<sup>-1</sup>, which is in reasonable agreement with estimates made by Donovan and Husain<sup>2-4</sup>, and is some four times faster than the diffusion of xenon in argon, calculated on the basis of the first approximation Chapman-Enskog equation<sup>10</sup>. The value of  $A_{nm}$  was found to be  $22 \pm 6$ /sec, which can be compared with Garstang's<sup>8</sup> calculated value for this quantity of 7.8/sec. Investigation of collisional quenching has been carried out by monitoring the spontaneous emission in the presence of various added gases, and this work will be presented in a later publication.

Polanyi *et al.*<sup>11</sup> have investigated the steady spontaneous emission from  $I(5^2P_{1/2})$  in the classical photolysis of hydrogen iodide. Pimentel and his co-workers<sup>12,13</sup> have studied the stimulated emission from  $I(5^2P_{1/2})$  in the flash photolysis of a number of iodides.

We thank Professor E. A. Abrahamson for laboratory facilities and many stimulating discussions. One of us (J. R. W.) wishes to thank the U.S. National Science Foundation for a graduate traineeship during the tenure of which this work was carried out, and the other (D. H.) the United States-United Kingdom Educational Commission for a Fulbright Travel Award. This work was supported by a contract of the United States Atomic Energy Commission.

## PHYSIOLOGY

## Motoneurone Depression by Norepinephrine

Dahlström and Fuxe have shown histochemically that norepinephrine (NE) is localized in a pathway from the brain stem to the spinal cord with terminals predominantly in the dorsal and ventral horns<sup>1</sup>. Biochemical investigations demonstrating the release of NE from the spinal cord by stimulation of descending tracts<sup>2</sup> and almost complete disappearance of NE below a spinal transection<sup>3</sup> provide additional evidence for a descending NE pathway. A pharmacological investigation of the sensitivity of neurones in the spinal cord had previously reported<sup>4</sup> that interneurons were not sensitive to the electrophoretic administration of NE in barbiturate anaesthetized cats (the effect of NE on motoneurons was apparently not investigated). Because it is known that barbiturate anaesthesia can reduce or abolish pharmacological responses in the spinal cord<sup>5,6</sup>, we reinvestigated this problem in decerebrated cats and a few cats anaesthetized with ether and found that Renshaw cells and a number of interneurons are sensitive to NE (refs. 7 and 8). Similar findings have now been reported by other investigators<sup>9,10</sup>. During the course of these investigations, the extracellular action potentials of single motoneurons were only occasionally recorded; the investigation of these cells revealed that NE depressed the firing of some motoneurons.

The experiments were performed in the sixth lumbar to first sacral segments of the cat spinal cord. Five-barrel glass micropipette electrodes with tip diameters of 2–8  $\mu$  were used to record extracellular neuronal action potentials and to administer drugs by electrophoresis at the site of recording. Details of the experimental procedures have already been reported<sup>8</sup>. Motoneurons were identified by antidromic invasion following stimulation of the central end of transected ventral roots. Because  $\alpha$  motoneurons did not fire spontaneously under these experimental conditions, the effect of NE was tested on antidromic action potentials, neuronal firing induced by an excitant amino-acid, and injury discharge. In eleven of twenty-five  $\alpha$  motoneurons thus investigated, neuronal firing was depressed by electrophoretically administered NE.

In contrast with our findings on Renshaw cells<sup>7</sup>, which were more often depressed but occasionally excited by NE, none of the  $\alpha$  motoneurons so far investigated showed any facilitation of firing during the administration of NE.

When the effect of NE was investigated on extracellularly recorded antidromic spikes, it was found that in some motoneurons the *A-B* inflexion<sup>11</sup> on the rising phase of the spike became more prominent. After the increased *A-B* break, a blockade of the antidromic invasion of the *B* spike was observed, as illustrated in the second column of Fig. 1, which indicates that NE decreased the excitability of the somedendritic membrane<sup>12</sup>. Consistent *A-B* invasion returned within 5–30 sec after the administration of NE, but recovery was accompanied by a prominent *A-B* break (third column of Fig. 1) before the spike returned to the control configuration. The bottom two records in Fig. 1 illustrate controls and these show that current of the same magnitude applied through a sodium chloride barrel of the same micropipette has no appreciable effect on the antidromic spike.

When smaller (negative) antidromic spikes were recorded, we investigated the effect of NE on the tonic firing induced by the iontophoretic ejection of the excitant amino-acid—DL homocysteic acid—from another barrel of the microelectrode. In some cases, the electrophoretic administration of NE reduced the frequency of the firing induced by the amino-acid. The upper portion of Fig. 2 shows the antidromic action potential of a single motoneuron on the negative field potential generated by groups of these cells; the stimulus was adjusted to threshold for the neurone so that the all-or-none spike can be seen. The lower portion of Fig. 2 shows a polygraph record of the amino-acid induced firing of the same motoneuron and the depression of this firing produced by the electrophoretic administration of NE with 75 n.amp of current. The same magnitude of current through a sodium chloride barrel of the electrode had no effect. Norepinephrine also depressed the injury discharge of some motoneurons, but because of the short duration of this discharge, there was never sufficient time after the pharmacological test to test for the possibility of electrotonic effects of current.

In addition, acetylcholine and serotonin were administered to two of the motoneurons sensitive to NE, with

Fig. 1. Effects of electrophoretically administered norepinephrine (NE) on the extracellularly recorded antidromic spike of an  $\alpha$  motoneuron. In each column, successive oscilloscope sweeps progress from bottom to top; each sweep is one second apart. Negativity of the microelectrode gives an upward deflexion. Top. The sweeps in the second column were recorded during the administration of NE ejected by a cationic current of 100 n.amp, the record beginning 12 sec after the onset of the current. Sweeps in the third and fourth columns begin 26 sec and 45 sec, respectively, after the end of the electrophoretic current. Bottom. The effect of 100 n.amp of anodal and cathodal current applied through a sodium chloride barrel of the same micropipette.

Fig. 2. *Top*. Antidromic action potential of a motoneurone recorded extracellularly; the stimulus was adjusted to threshold so that all-or-none spikes can be seen. *Bottom*. Polygraph record of the tonic firing of the same motoneurone induced by the electrophoretic ejection of DL-homocysteic acid from one barrel of the microelectrode. Norepinephrine was administered for the period between the arrows by an electrophoretic current of 75 namp. Calibration scale at the left is in impulses per sec.

similar magnitudes of electrophoretic current, but no effect was observed; however, this sample is too small to draw any conclusions regarding the possibility of sensitivity of motoneurons to these substances.

Dahlström and Fuxe<sup>1</sup> used retrograde degeneration to establish whether the cell bodies of  $\alpha$  motoneurons receive NE terminals; they found that NE terminals form close contacts with the cell bodies and processes of some  $\alpha$  motoneurons. Although several criteria must be satisfied for transmitter identification<sup>13</sup>, the presence of NE terminals on motoneurons and the demonstration of the sensitivity of motoneurons to NE suggest that NE may function as a transmitter for at least some  $\alpha$  motoneurons.

### Motor Effect of Adrenaline on the Rat Uterus

ADRENALINE has an inhibitory effect on the rat uterus in all stages of the reproductive cycle, and this suggests that the rat uterus contains only  $\beta$  adrenergic receptors. It was of interest, therefore, to test whether adrenaline reversal could be obtained in this organ, because such a reversal would imply the presence of  $\alpha$  adrenergic receptors.

The phenomenon was investigated in rats treated with stilboestrol, and in ovariectomized rats treated with progesterone. Mature female Wistar rats weighing about 200 g were used. Stilboestrol was given subcutaneously in a single dose of 0.5 mg dissolved in arachis oil, and the animals were used 40 h later. Ovariectomy was

carried out by the dorsal route under ether anaesthesia; 0.5 mg of stilboestrol was then given, and for the following 5 days progesterone was given intraperitoneally dissolved in arachis oil in a dose of 2.5 mg/kg, and the animals were used on the day after the end of treatment.

The animals were stunned by a blow on the head and bled out; the uterus was removed and suspended in a 25 ml. organ bath containing mammalian Ringer-Locke solution at 36.5° C, and through which air was passed in a continuous stream. Readings were made on a smoked drum with an isotonic lever. Normal contractions appeared within 5 min, and the preparation was left to equilibrate for a further period of 30–60 min.

Adrenaline reversal was investigated under the influence of isoprenaline, in accordance with the method used by Butterworth<sup>1</sup> in studies of the cat blood pressure. Isoprenaline in a concentration of 0.1  $\mu$ g/ml. caused an immediate and total inhibition of the intrinsic rhythm for a period of 7–14 min. Thereafter the uterus contracted irregularly at about 10–30 per cent of the original extent. The further addition of isoprenaline at this stage did not inhibit these contractions. A typical experiment showing this escape from the action of isoprenaline is shown in Fig. 1. Escape was obtained in uteri from rats treated with stilboestrol, but in rats treated with progesterone inhibition remained complete for periods exceeding 60 min. The escape did not result from the breakdown of isoprenaline into a substance with motor activity because bath fluid from a preparation where escape had occurred caused maximum inhibition of a fresh preparation; nor could it be ascribed to changes in pH.

During the inhibition and escape from the action of isoprenaline the effect of adrenaline in a concentration of 0.1  $\mu$ g/ml. showed that during most of the quiescent phase adrenaline was without effect. The addition of adrenaline towards the end of the quiescent phase, or during the recovery period, produced a motor response which increased in magnitude as the addition of adrenaline was delayed, and the maximum contraction amounted to 80 per cent of the original intrinsic rhythm when the adrenaline was added after 50 min. The results are shown in Fig. 2, curve A.

In rats treated with progesterone no response was obtained to the addition of adrenaline, even when it was added 60 min after the onset of inhibition. The results are shown in Fig. 2, curve B, and are represented by a straight line along the axis of the abscissa.

These results therefore show that adrenaline reversal can be obtained under the influence of isoprenaline in the

Fig. 1. Uterus from a rat treated with stilboestrol. A, Isoprenaline added to a final concentration of 0.1  $\mu$ g/ml.; B, onset of escape; C and D, repetition of addition of isoprenaline; E, wash. Time marker, 30 sec.

Fig. 2. Motor response of rat uterus to adrenaline under the influence of isoprenaline. *A*, Animals treated with stilboestrol; *B*, animals ovariectomized and treated with progesterone. Ordinate, height of contraction produced by adrenaline as a percentage of the height of the original intrinsic contraction; abscissa, time in minutes after onset of isoprenaline inhibition. Each point represents a result obtained with one horn of a uterus.

rat uterus in animals treated with stilboestrol, and not in animals treated with progesterone.

According to the receptor hypothesis, these results mean that  $\alpha$  receptors are present in the rat uterus in animals treated with stilboestrol, but are absent or masked in animals treated with progesterone. If the  $\alpha$  receptors are anatomical entities, it seems very improbable that they could appear and disappear in this manner; if receptors are closely related to enzymes, however, then treatment with stilboestrol for 40 h would afford sufficient time for such an enzyme to be induced. In this case the enzyme would probably not be induced in the presence of progesterone.

The form of curve *A* in Fig. 2 may be explained by postulating that a substance with motor activity accumulates in the uterus during the period of isoprenaline inhibition, and is liberated by the addition of adrenaline; the amount liberated, and therefore the height of contraction, would be related to the time of addition of adrenaline during isoprenaline contact.

### Islet Formation in the Cortex of the Human Thymus

MORPHOLOGIC units consisting of a central macrophage-like cell surrounded by several lymphocytic or plasma cells, and termed islets, are seen in lymph nodes<sup>1</sup>, and in cultures of lymph node cells<sup>2</sup>, blood lymphocytes<sup>3,4</sup> and thymic cells<sup>5</sup>. Islets formed by lymphocytes and (or) eosinophilic and neutrophilic leucocytes are observed surrounding degenerating mononuclear cells containing antigens<sup>6</sup>.

It is the purpose of this paper to emphasize that a phenomenon similar to islet formation is frequently seen in the cortex of thymuses obtained at autopsies of infants and young children. In such thymuses, there is an obvious, though not very marked, destruction of cells in the thymic cortex. Pycnotic cells and small haematoxylin-positive particles of chromatin are seen scattered in the cortex.

Fig. 1. Islets in different phases of development in the cortex of a human thymus. Haematoxylin and eosin section,  $\times 160$ . On the right is an islet formed by several deeply stained small and medium-sized lymphocytes. On the left are two islets in an early stage of development. In the upper islet there is a large cell with a pale nucleus and abundant cytoplasm containing a small lymphocyte and two haematoxylin-positive nuclear particles. The lower islet shows lymphocytes just beginning to invade the islet.

Besides these there are, in most of the cases, peculiar oval areas containing homogenous masses of dead cells and often a large cell with a large pale nucleus and abundant cytoplasm (Fig. 1). These areas are infiltrated by lymphocytes resulting in the formation of islets (Fig. 1). The number of the cells in these islets varies greatly. Morphologically, the cells invading the islets are similar to small and medium-sized lymphocytes (thymocytes). Occasionally these cells stain with haematoxylin more intensely than the other lymphocytes. Some islets seem to be demarcated from the surrounding tissue by a thin membrane.

The hypothesis that RNA (ref. 7), breakdown products of DNA or other agents mediating information are obtained by the lymphocytes in the area of islets seems attractive, but definite evidence for such a theory is lacking. It is possible, at least in the thymus, that the lymphocytes which infiltrate the islets are destroyed; the unknown fate of thymic lymphocytes under stress conditions might so be explained. Whatever the significance of the islets is, the observations presented seem to indicate that the thymus is not principally different from the other lymphoid organs in the capacity to form islets.

This investigation was supported in part by grants from the U.S. Public Health Service.

### Mechanisms of the Crayfish Tail Flick

THE escape reaction of the crayfish consists of a rapid backward swimming movement brought about by powerful flexion of the abdomen. In the course of a primarily anatomical re-investigation (as yet unpublished) of the musculature responsible for this flexion in the crayfish *Procambarus clarkii*, it was observed that some 40 per cent of the cross-sectional area of the main flexor musculature is contributed by three muscles which both arise and

insert largely or entirely dorsal to the inter-segmental hinge. These are the central, transverse and dorso-lateral muscles, in the terminology of Daniel<sup>1</sup>. The expected "direct" action of such muscles would be extension rather than flexion; that so large a proportion of the flexor musculature is apparently "indirect" in its action was considered to be of a sufficiently general physiological interest to be presented separately from the main body of the work.

The anatomy of the main flexor muscles is shown diagrammatically in Fig. 1; the superficial flexors have been omitted from this discussion because they have been shown<sup>2</sup> to be purely tonic in action and thus not involved in the mechanism of the very rapid tail flick. The paired central muscles (*C.*) arise on the ventral surface of the transverse membrane (*Tr. mb.*) which crosses the segment at this level; they then twist ventro-laterally through the dorsally directed loop formed by the muscles in the anterior oblique "series" (*A i, ii* and *iii*; see also Fig. 3) and divide into two heads. Of these, the larger axial head (*C. ax.*) inserts on the underside of the next posterior transverse membrane, while the smaller transverse head (*C. trans.*) forms a mid-line inscription with the fibres of its opposite number on the other side of the body. The transverse muscles (*T.*) arise laterally on the under side of the transverse membrane and insert, with the transverse head of the central muscle, at the mid-line inscription (shown cross-hatched in Figs. 1A and 2A) which appears to be a ventral extension of the medial part of the transverse membrane. The three heads of the dorso-lateral muscle (*D-L*, Fig. 1B) also run transversely but arise and insert on the dorsal side of the transverse membrane. Each anterior oblique "series" was considered by Schmidt<sup>3</sup> to be a single muscle extending over three segments; however, the existence of clear inscriptions within each "series" shows that each consists of three separate segmental muscles connected end to end. Within any one segment three of these muscles (*A i, ii* and *iii*) are found, corresponding to the component muscles of three consecutive "series". In this figure only one "series" is shown. While the inscription between *A i* and *A ii* is not laterally connected to any skeletal part, the other two inscriptions appear to provide functional attachments for the *A* "series", the inscription between *A ii* and *A iii* being firmly attached ventrally and the

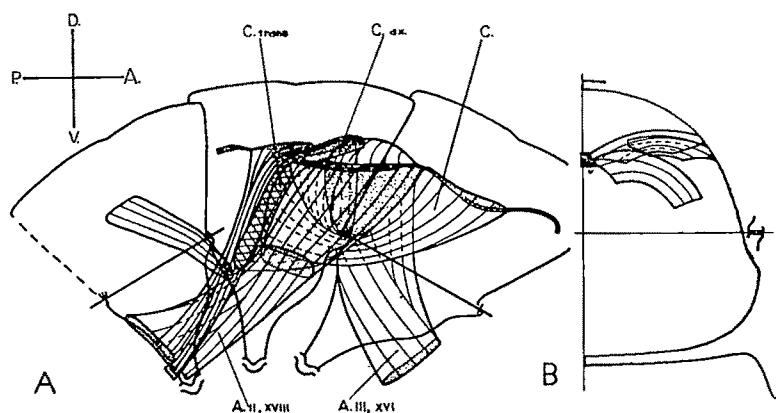

Fig. 2. The crayfish abdominal flexor musculature in the flexed position. A, Medial view of the second, third and fourth abdominal segments. B, Anterior view of the third abdominal segment.

more dorsal inscription between *A iii* and *A i* being continuous with the transverse membrane. The posterior oblique muscles (*P.*) run ventrally from the transverse membrane to insert with the *A ii* muscles at their inscription with the *A iii* muscles of the next posterior segment. The auxiliary muscles (*Aux.*) arise immediately lateral to the *A iii* muscles of the same segment and, at the same inscription, they insert on the lateral tergal wall. It should be noted that in this complex muscle system only this small auxiliary muscle is wholly inserted directly on to the skeleton.

The principal functional attachments of the main flexor musculature are thus: *a*, the strong ventral inscriptions, which are firmly attached to a thickened region of the ventral surface membrane just posterior to each sternal bar (*St.*); *b*, the lateral attachments of the transverse membranes to the dorso-lateral tergal walls (*Tr. mb. l.*).

When this musculature is examined in the fully flexed position (see Fig. 2), certain interesting points emerge which help to clarify the function of the indirect muscles. First, the loop formed by the central muscle remains ventral to the hinge point even in full flexion. While this criterion is satisfied, contraction of the central muscle can be expected to produce a flexor force by its action around the "pulley-wheel" provided by the contracting muscles of the anterior oblique series (see Fig. 3). Second, the medial part of the transverse membrane is seen to have shifted dorsally relative to the position of the inter-segmental hinge. This initially surprising result of flexor action can be more readily understood when it is realized that the raising of the transverse membrane would be the sole function of the rather powerful dorso-lateral and transverse muscles if these alone were stimulated. The importance of this action in terms of the tail flick mechanism appears to lie in its effect on the changes in length of the direct muscles. Calculations based on measurements obtained from camera lucida drawings suggest that the observed dorsalward movement of the transverse membrane effectively halves the change in length of these muscles required to produce flexion. Because the mechanical situation is not greatly altered, a virtual doubling of the tail flick velocity might be expected.

It should be emphasized that this investigation has been based on the steady-state positions of full flexion and extension. The dynamic properties of this system will depend on the details of the timing of impulse arrival and on the rates of rise of tension in different muscles; the overall properties of the single functional unit

Fig. 1. Internal view of the crayfish abdominal flexor musculature in the extended position. A diagrammatic reconstruction prepared from camera lucida drawings. A, Medial view of the second, third, and fourth abdominal segments. B, Anterior view of the third abdominal segment (only the medial part of the transverse membrane is shown in this figure). See text for explanation of abbreviations. The lines drawn across the second and fourth segments are drawn through the intersegmental hinges, the positions of the hinges being marked by the short vertical bars. The parts of the transverse membrane and all inscriptions are shown stippled, with the exception that the mid-line inscription between the lateral halves of the transverse-running muscles is cross-hatched.

Fig. 3. Diagrammatic representation of the "pulley-action" occurring in the flexor musculature of the crayfish abdomen. Dimensions used were derived from camera lucida drawings. *A*, Second, third and fourth abdominal segments in the extended position. *B*, The same segments in the fully flexed position.

formed by the *A i* and *A ii* muscles connected in series are still an interesting problem, particularly as these muscles are known to be innervated from different segments (unpublished work).

### Calcium Action at an Inhibitory Synapse

THE transmitter substance of the crossed olivo-cochlear fibres has not been identified<sup>1</sup>. The previously known actions of these inhibitory fibres are blocked by strychnine<sup>2</sup> and it may also be of significance that the fibres and their endings apparently contain acetylcholinesterase<sup>3</sup>.

The release of acetylcholine at the motor nerve terminals in the frog and the rat depends directly on the presence of calcium<sup>4</sup> and it has been reported recently that perfusion of the scala tympani in the cochlea of the guinea-pig with solutions which contained calcium in increased concentrations caused increased changes of sound evoked potentials. Thus cochlear microphonics and negative summing potentials were increased while the whole nerve action potential was decreased<sup>5</sup>.

The present investigation is concerned with the action of calcium and strychnine on the slow negative potential that

is recorded from the endolymph of the cochlea when the crossed olivo-cochlear fibres are stimulated repetitively. Inhibition of activity in the cochlear nerve by the crossed olivo-cochlear fibres is considered to be caused by the direct action of these fibres on outer hair cells, and the slow potential of the present investigation is considered to represent the post-synaptic, inhibitory activity of outer hair cells, generated by efferent endings<sup>6</sup>.

We used ten cats which were anaesthetized with pentobarbitone sodium and paralysed with gallamine triethiodide. The crossed olivo-cochlear fibres were stimulated electrically in the floor of the fourth ventricle. Cochlear potentials evoked by such stimulation, and by sound presented to the ear, were recorded from the scala media, with microelectrodes of resistance 1-5 MΩ filled with 3 molar potassium chloride solution. The membrane of the round window was removed. Perilymph was sucked away from the scala tympani to expose the basilar membrane so that the microelectrode could be pushed through the cochlear partition into the endolymphatic space under relatively good visual control. In control experiments, cochlear potentials were recorded to ensure that slight variations of the level of the perilymph in the scala tympani, or substitution of part of the perilymph with artificial perilymph, did not influence the results. The following solutions were used as artificial perilymph. Solution *A*: sodium chloride 125 mmoles, sodium bicarbonate 25 mmoles, potassium chloride 3.5 mmoles, calcium chloride 1.3 mmoles, magnesium chloride 1.14 mmoles, sodium dihydrogen orthophosphate 0.51 mmole, urea 130 mg/l., glucose 610 mg/l.<sup>7</sup>. Solution *B*: sodium chloride 140 mmoles, sodium bicarbonate 12.5 mmoles, sodium dihydrogen orthophosphate nil and the other components as in Solution *A*. Strychnine hydrochloride was added to Solution *A* or Solution *B* to a concentration of 0.012 mmoles, that is, strychnine hydrochloride  $5 \times 10^{-6}$ . The calcium concentration was increased by addition of calcium chloride, with or without deletion of an equivalent amount of sodium chloride. The solutions were heated to 38°-40° and equilibrated with 'Carbogen' (5 per cent CO<sub>2</sub>, 95 per cent O<sub>2</sub>) immediately before their application to the scala tympani with a thin glass tube.

In five animals strychnine was applied to the scala tympani. In one of these, strychnine was used twice before the application of a solution with an increased content of calcium, in one animal once before and once after such an application, and in three animals after calcium only. The amplitude of the slow potential evoked by efferent stimulation decreased by at least 80 per cent after the application of only strychnine and by at least 65 per cent when strychnine followed on calcium with an interval of 30 min or more. Strychnine also lengthened the latency of the slow potential. These effects of strychnine began to appear within 20 sec in two experiments and were always fully developed within 2-3 min. In two experiments, in which artificial perilymph was repeatedly applied to the scala tympani after strychnine, the effects of strychnine began to reverse in 21-24 min and in one of these experiments the slow potential had regained 90 per cent of its original amplitude in 40 min. Thus, because strychnine in low concentrations in the scala tympani partly blocks the generation of the slow potential under investigation, this potential is caused by efferent synaptic activity in the organ of Corti, by the same order of probability as are the cochlear actions previously ascribed to such activity<sup>2</sup>.

Results from a typical experiment with calcium are illustrated in Fig. 1. The potentials under investigation were reasonably stable (Fig. 1, *A*, *B* and *D*) and were not altered by the substitution of perilymph in the scala tympani by Solution *A* in which 20 mmoles of sodium chloride had been replaced by 40 mmoles of sucrose (Fig. 1, *B*, *C*). When 20 mmoles of sodium chloride had been replaced by 10 mmoles of calcium chloride, however, the slow potential evoked by efferent stimulation was

changed (Fig. 1, *D, E*). Both the latency and the time of rise were shortened, and the falling phase prolonged. The corresponding changes produced in another animal when 5 mmoles of calcium chloride had been added to Solution *B* in exchange for perilymph are illustrated in Fig. 2. The effects of calcium began to appear in one experiment within 10 sec and were always fully developed within 1–4 min. The effects began to reverse spontaneously in 17 to 25 min in some experiments; in others the effects were still fully maintained 25–30 min after the application of the solution which contained high calcium.

In all animals, application to the scala tympani of Solution *A*, or *B*, with an increased content of calcium, produced shortening of the latency, shortening of the rise time required to reach a maximum, and a prolongation of the falling phase of the slow potential from crossed efferent stimulation. Because such changes have not occurred spontaneously in any of the animals in which potentials evoked by efferent stimulation have been investigated<sup>4</sup>, they are most likely the consequence of an increase of calcium ion concentration within the organ of Corti.

Fig. 1. Column 1 shows the slow negative potentials evoked by repetitive electrical stimulation of the crossed olivo-cochlear fibres in the brain stem (duration of stimulation is indicated by arrows). Column 2 shows the cochlear microphonic (CM) and the summating potential (SP) evoked by sound stimulation. The SP discussed here corresponds to the initial asymmetry of the full size CM relative to the baseline. All the records were taken with the microelectrode in one position in the endolymph of the cochlea. *A*, Control, perilymph in scala tympani. *B*, Control, 60 min after *A*. *C*, Control, 10 min after *B*. The perilymph of the scala tympani had been partly replaced by artificial perilymph (Solution *A*, minus sodium chloride 20 mmoles, plus sucrose 40 mmoles). Pictures were taken 3 min after the replacement. Note that the responses to both stimuli were unchanged. *D*, Control, 15 min after *C*. *E*, 15 min after *D*. The perilymph had been partly replaced by a test solution with an increased content of calcium chloride (Solution *A*, minus sodium chloride 20 mmoles, plus calcium chloride 10 mmoles). Pictures were taken 3 min after the replacement. The time calibration is common to all the records. Each voltage calibration is common to all records within each of the columns. The time constant of the recording system was 100 msec. Negativity is upwards.

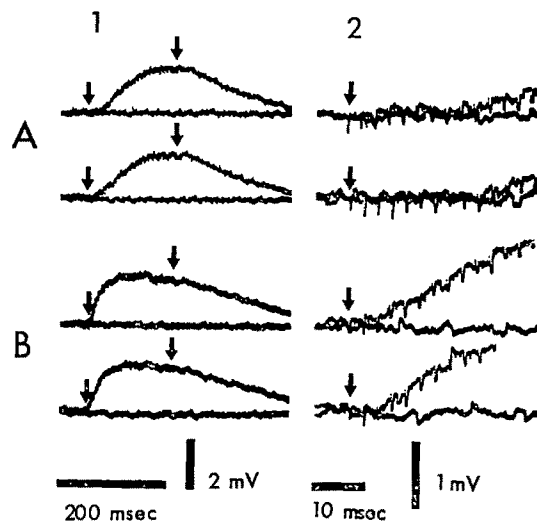

Fig. 2. Column 1 shows the full time course of slow negative potentials from efferent stimulation (duration of stimulation is indicated by arrows). Column 2 shows the initial course of such potentials, displayed with a fast sweep (start of stimulation indicated by arrow). All the records were taken with the microelectrode in one position in the endolymph of the cochlea. *A*, Control, perilymph in scala tympani. *B*, 7–8 min later than *A*. The perilymph had been partly replaced by a test solution with an increased content of calcium chloride (Solution *B* plus calcium chloride 5 mmoles). Pictures taken 2.5 min (*B2*) and 3 min (*B1*) after the replacement. See text for results. Note that time calibration and voltage calibration are different for the two columns. The time constant of the recording system was 100 msec. Negativity is upward.

There was no consistent change of the cochlear microphonics with increase of the calcium content in the scala tympani. The summing potentials, however, showed a small change towards the negative side in seven out of eight cats in which the summing potential was observed: these changes were generally about twice the size of that in Fig. 1, *D, E*. Such changes were as a rule not found when artificial perilymph was applied to the scala tympani, and were probably also caused by the increased content of calcium. If so, calcium may have acted directly on the hair cells generating the summing potential, or indirectly through efferent endings impinging on these hair cells.

These new findings lead to the conclusion that calcium participates in the synaptic mechanism of the crossed olivo-cochlear inhibitory efferents and strongly suggest that release of transmitter substance at this synapse, as at the neuro-muscular junction<sup>4</sup>, is dependent upon calcium.

### Induction of Tumours in Denervated Skin

It has been shown that the number of fine axons in close relationship with the epidermis of human skin increases *pari passu* with a rise in the mitotic index in the germinal layer<sup>1,2</sup>. These observations prompted us to compare the rate of tumour induction by chemical carcinogenic agents in comparable zones of healthy as well as denervated

skin in the same animal, because it has been shown that in completely denervated skin the mitotic index falls<sup>3</sup>.

The right ears of ten Dutch male rabbits between 5 and 6 months old were completely denervated by methods suggested previously<sup>4-7</sup>, under 'Nembutal' and ether anaesthesia. In four animals both the inner and outer surfaces of both ears were evenly painted with 2 per cent methylcholanthrene dissolved in benzene (2) and liquid paraffin which covered comparable areas of skin previously outlined by indian ink. In four more animals the agent used for painting was 2 per cent 9,10-dimethyl-1,2-benzanthracene (DMBA) dissolved in benzene. In each case a standard volume of solution was placed in the centre of the area outlined, using a Pasteur pipette, with which it was evenly spread and allowed to dry. This was done twice daily for 2 weeks and twice weekly for the next 4 or 5 months. In two animals in each group the hairs within the treated area were removed by shaving and in the others the hairs were plucked out with forceps.

The results are set out in Tables 1, 2 and 3.

8	10	7	37	Nil

From Table 1 it can be seen that (a) 2 per cent DMBA is a more effective and consistent tumour inducing agent than 2 per cent methylcholanthrene in experiments of this kind, a fact which has already been established; (b) both carcinogenic agents induced tumours more readily in the denervated than in the control ears, and in any given animal the tumours appeared earlier on the denervated side; (c) on the control side tumours appeared more quickly on the inner than on the outer aspects of the ears; (d) there seems to be no obvious relationship between the rate of tumour formation and hair growth induced by plucking in this short series of animals.

Table 2 shows that (a) tumour growth was faster on the right (denervated) ear than on the left ear after the use of DMBA. The same was true in the case of methylcholanthrene, and although the number of tumours grown was few the trend was in the same direction; (b) tumour growth was slower on skin in the inner surface of the ear, and this was the case in both control and denervated ears.

Table 3 shows that ulceration occurred more often in denervated ears. At the start, the tumours which were induced looked like keratoacanthomas; later some of them ulcerated (Fig. 1), but histologically they could not be differentiated from squamous cell carcinomas either before or after ulceration (Fig. 2).

Fig. 1. Ulcerated tumour on inner surface of denervated rabbit ear induced by applying DMBA for 5 weeks.

Fig. 2. Section (stained with haematoxylin and eosin) which shows non-mature 'Pearl' and atypical cells showing individual keratinization.

Fig. 3. Section (stained with silver) which shows a nerve bundle between masses of tumour cells. Many axons are degenerating and towards the right neural elements have almost disappeared.

In sections stained with silver to display the neural elements<sup>8</sup>, only a few very fine axons were seen in some of the sections from the denervated side, but on the control side numerous fine axons and Schwann cells surrounded the invading cells. Within the tumour nerves were present only in the early stages of its development; later degenerating remnants were seen (Fig. 3) and later still no neural elements at all.

Despite the small number of animals so far examined in detail, some interesting facts have emerged. Tumours are induced more rapidly in completely denervated rabbit ears as compared with their opposite ears which served as controls. Tumours are also induced more rapidly in skin of the inner aspects of control ears. This is also interesting, for skin on the inner surface of the ear is far less densely innervated than skin on the outer surface. Complete denervations of the rabbit ear led to alterations in the blood supply of the skin on both of its surfaces, yet tumours grew faster in the skin of the inner aspects of the denervated ears, which in any case have a poorer blood supply than the outer surfaces. On the control side, however, the opposite was the case. Tumours grew more slowly in the skin of the inner aspects, so that the relevant factor concerned with tumour growth here must be connected

with an interference with the nerve supply and not with the blood supply.

## Iron Absorption and Retention in Man

Conrad and Crosby<sup>1</sup> have shown that, in normal rats, a proportion of the iron which has been absorbed from the intestinal lumen is retained in the epithelial cells of the intestine, and lost with the faeces in the course of the normal desquamation of these cells. In rats with iron deficiency, scarcely any iron is retained in the intestinal epithelial cells.

Conrad and Crosby believe that a similar mechanism acts in man; they reached this conclusion on the basis of a study in which normal subjects and patients with iron deficiency received an oral test dose of radioactive iron and with carmine red. They found that the excretion of radioactivity in the faeces of normal subjects persisted considerably longer than the excretion of carmine red. In patients with iron deficiency, however, the faecal excretion of radioactivity and that of carmine red lasted about the same length of time. These findings suggested that the conventional clinical methods of measuring iron

absorption from the intestine after a given interval—usually 10–15 days<sup>2</sup>—do not determine iron absorption but iron retention, that is, the quantity of iron absorbed minus the quantity of iron which is excreted in the faeces after absorption.

Our objective was to study the absorption and ultimate retention of iron in man. For this purpose we used a tracer dose of radioactive iron and barium. The barium was added because, in the form of barium sulphate, it is believed not to be absorbed from the intestinal tract and can consequently serve as an inert indicator. Oral administration of barium-131 sulphate and iron-59 sulphate might therefore make it possible to assess the absorption of iron from the intestinal lumen by measuring the proportions of iron-59 and barium-131 in the test dose and the faeces<sup>3</sup>. By determining the total quantity of iron-59 excreted in the faeces it should be possible to determine the ultimate iron retention. The experiments were carried out in three normal healthy subjects with normal haemograms, normal serum iron concentrations and serum iron saturation percentages; two patients with sideropenic anaemia and two with iron overload (patient 6 had familial red cell aplasia with secondary haemochromatosis after some 150 blood transfusions, normochromic macrocytic anaemia, a serum iron concentration of 274 µg/100 ml. and a serum iron saturation percentage of 88; patient 7 had hereditary hypochromic sideroachrestic anaemia with haemosiderosis, a serum iron concentration of 185 µg/100 ml. and a serum iron saturation percentage of 86).

The test dose administered was 15 µc. barium-131 and 170 mg barium sulphate, 5 µc. iron-59 and 1 mg iron in the form of iron sulphate, 10 mg ascorbic acid and 2 g carmine red. The technical details will be published elsewhere<sup>4</sup>. The test results in the aforementioned patients are shown in Tables 1, 2 and 3. The results suggest that

\* Total iron absorbed minus iron retention after 10-15 days.

barium sulphate is not absorbed; this was later confirmed with a whole-body counter\*. In the patients with iron deficiency (Table 2: Nos. 4 and 5), the iron-59 disappeared from the faeces only slightly later than did barium-131; this indicates that iron-59 sulphate and barium-131 sulphate have about the same rate of intestinal passage.

Absorption of iron from a test dose occurs for the most part within the first 2 h; the remaining absorption is believed to occur up to 20 h after administration of a test dose<sup>6</sup>. The proportionate radioactivity of iron-59 and barium-131 in the faecal samples shows that this coefficient is always lowest in the first sample to show carmine red; in samples taken on subsequent days this coefficient increases, and this may indicate that epithelial cells labelled with iron-59 enter the intestinal lumen soon after the absorption of iron-59 by the intestinal mucosa. This is plausible if we assume that in man both young and old epithelial cells of the intestinal villi absorb iron. This is known to be the case in rats. The oldest epithelial cells are likely to be lost in the intestinal lumen soon after absorption of iron; if they contain iron-59, they are bound to influence the ratio iron-59:barium-131. We have therefore calculated the percentage of absorption from the first faeces stained by carmine red. The ratio of iron-59 to barium-131 in subsequent samples of the faeces increased least in the patients with sideropenic anaemia (Table 2); in these patients, apparently, almost all iron-59 absorbed is directly passed by the epithelial cells of the intestinal mucosa and released into the blood.

In normal test subjects and patients with iron overload, radioactive iron is still present in the faeces long after barium-131 has ceased to be demonstrable. The rate at which the faeces pass through the intestinal tract varies, but faecal excretion of barium-131 is usually completed within 6 days. As mentioned before, the absorption of iron from the test dose is believed to occur within the first 24 h<sup>5</sup>. If it is true that the life span of epithelial cells of the human intestinal mucosa is 3-6 days<sup>6,7</sup>, then iron-59 found in the faeces 13 days or more after oral administration of iron cannot originate from the epithelial cells which first absorbed the iron-59. Possibly, this iron-59 enters the faeces so late because, after absorption, when it starts to circulate in the organism, it is re-distributed and in part taken up by newly formed cells of the intestinal mucosa<sup>8</sup>. These cells are desquamated into the intestinal lumen after a few days. Another possibility is that a proportion of the iron-59 in desquamated intestinal epithelial cells is again absorbed lower in the intestinal tract. Part of this re-absorbed iron-59 could then re-enter the faeces with desquamated epithelial cells. A proportion of the iron-59 in the faeces also probably originates from macrophages loaded with iron, which play a part in the absorption and re-distribution of iron in the organism<sup>9</sup>. Tables 1-3 show that absorption was greatest in the two patients with iron deficiency, in which nearly all iron absorbed was also retained (Table 3). Absorption in the normal test subjects varied from 20 to 47 per cent of the dose of iron-59 administered, and retention varied from

9 to 27 per cent. The difference in absorption and retention was about as great as that in the two patients with iron overload, that is, up to 20 per cent of the dose of iron-59 administered. One of the normal test subjects absorbed nearly as much (47 per cent) as one of the patients with sideropenic anaemia (52 per cent). The ultimate retention percentage (Table 3) shows, however, that in the patients with iron deficiency nearly all the iron absorbed was retained in the organism. In the normal test subjects, a large amount of the iron absorbed was not passed by the intestinal mucosa but entered the faeces.

The results of the tests described indicate that, in man, more iron is normally absorbed than is ultimately retained in the organism. Only in patients with sideropenic anaemia is the retention of orally administered iron nearly as great as the absorption. These tests confirm the assumption made by Conrad and Crosby on the basis of the results of their tests with radioactive iron in rats and with radioactive iron and carmine red in man.

With the aid of an oral test dose of iron-59 sulphate and barium-131 sulphate, the iron absorption percentage can be rapidly and easily calculated without the need for quantitative collection of faeces. In order to determine the ultimate retention of iron-59 in the organism after an oral test dose of iron-59, however, it is necessary either to make quantitative determinations of faecal iron-59 or to establish with the aid of a whole-body counter how much iron-59 remains in the organism 2 weeks or more after administration of a test dose of radioactive iron.

### Meaning of Impedance Plethysmography

IMPEDANCE plethysmography is a method of measuring the resistive impedance of a limb segment. Nyboer<sup>1</sup> pointed out that the resistive impedance variation  $\Delta R$  during the heart cycle is proportional to the blood volume  $\Delta V$  transiently stored in the segment

$$\Delta V = -\rho \frac{l^3}{R_0^2} \Delta R$$

where  $\rho$  is the blood resistivity,  $l$  the length of the segment and  $R_0$  the mean steady value of the segment resistance. Nyboer<sup>1</sup> proposed a method of calculating the blood flow by extrapolating the post-systolic slope of the plethysmogram. This procedure is subject to some criticisms and may lead to wrong results.

We propose a quite different interpretation of the impedance plethysmogram.

The problem of pulsatile flow in arteries has been analysed from a biophysical standpoint by many authors. Womersley<sup>2</sup> pointed out that the radial expansion  $\xi$  of an artery during the pulse is not directly related to the pressure but to the average blood velocity  $\bar{v}$  (instantaneous mean value of the velocity in the section of the artery), to the resting radius  $r$  and the pulse-wave velocity  $c$  through the simple relation

\* Whole body counting was performed by the Radiological Workgroup, T.N.O., Arnhem.

$$\frac{\xi}{r} = \frac{\bar{v}}{c}$$

McDonald<sup>3</sup> showed that this relation can be clearly justified from the physical point of view, but it leads to an interpretation of the impedance plethysmogram quite different from that of Nyboer.

If we assume that the radial expansion  $\xi$  is very small in comparison with the radius of the artery<sup>4</sup>, we may put

$$\Delta V = 2\pi r \xi$$

so that

$$\xi = -\frac{\rho l}{2\pi r R_0^2} \Delta R$$

and the mean instantaneous velocity of the blood

$$\bar{v} = -\frac{\rho l c}{2\pi r^2 R_0^2} \Delta R$$

The instantaneous blood flow is given by

$$Q = \bar{v} \pi r^2 = -\frac{\rho l c}{2R_0^2} \Delta R$$

The resistive impedance variation  $\Delta R$  is thus proportional to the pulsatile flow, but the value of the constant of proportionality is a function of the velocity of the pulse wave. This velocity depends on the elastic behaviour of the artery, so that it is not possible to evaluate  $Q$  from the impedance plethysmogram without an independent measurement of  $c$ . The information that we may have

from the plethysmogram is only a value of the ratio  $\frac{Q}{c}$ .

As an experimental test, we have measured the mean flow in the segment of a limb for different values of  $c$ . The variation of the pulse wave velocity has been obtained by changing the transmural pressure of the arteries. As is well known, a reduction in the transmural pressure reduces the mean tension of the arterial wall. Arterial walls have elastomeric properties and the Young's modulus  $E$  largely varies with the tension<sup>5</sup>.

Because the pulse wave velocity is proportional to  $E^{1/2}$  (ref. 6), a reduction of the transmural pressure produces a reduction of  $c$ . We have measured the pulse-wave velocity in the segment by using the  $R$  pulse of the electrocardiogram as the external trigger of a double beam cathode-ray oscilloscope.

The  $y$  axes of the two beams are driven by the resistive impedance variations in two equal segments of the legs. In a segment of one of the thighs we have applied an external pressure with a pneumatic cuff. As the pressure is raised, the corresponding pulse is delayed and the amount of this delay is a measure of the velocity of the pulse wave (Fig. 1).

We have now measured the mean blood flow from the impedance plethysmogram in two segments, one in the thigh and the other in the leg on the same side for different

Fig. 1. Pulse-wave velocity as a function of external pressure in a segment of the thigh of a 14 year old boy.

Fig. 2. Blood flow in the thigh and in the leg of a 14 year old boy as a function of an external pressure applied to the thigh. ●, Flow calculated assuming a constant wave velocity of 5.40 m/sec; ×, flow calculated with the measured value of the velocity; △, flow in the leg.

values of the pressure. A cuff is applied between the electrodes of the plethysmograph on the thigh and the flow measured. The cuff has been found to produce a variation of  $R_0$  and  $l$  of less than 1 per cent in the range of pressures from 0 to 100 cm of water and we therefore think that the flow measurement is independent of passive effects due to the cuff. If the pulse wave has a constant velocity, the increased flow through the thigh segment with the applied pressure is quite paradoxical. On the other hand, the values of the pulse wave velocity measured directly give a constant flow up to the maximum value of the arterial pressure as might be expected.

The decrease in the calculated flow for external pressures up to 20 mm of mercury is due to the contribution of the venous pulse in the external venous system.

These results may be of some interest to clinicians, because impedance plethysmography is an excellent tool in the diagnosis of peripheral vascular disease.

## BIOLOGY

### Autoregulation of Release of Melanocyte Stimulating Hormone from the Rat Pituitary

MELANOCYTE stimulating hormone (MSH) enables amphibians such as the frog to change skin colour and thereby adapt to the environment. The function of this pituitary hormone in mammals such as the albino rat has not been established.

The release of MSH from the pituitary of the frog is controlled primarily by an area of the central nervous system—the hypothalamus. If the hypothalamus is destroyed, the frogs turn black<sup>1</sup>. These darkly pigmented frogs have increased amounts of MSH activity in their body fluids and decreased amounts of MSH activity in their pituitaries<sup>2</sup>.

There is evidence that the albino rat has a similar mechanism for the control of MSH release. The MSH content of a rat pituitary increases after injection of hypothalamic extracts<sup>3,4</sup>; it decreases selectively after

removal from direct hypothalamic influence<sup>6</sup> and after treatment with some of the same tranquilizers that cause frogs to darken<sup>6,7</sup>. Thus, in the rat as well as in the frog, it appears that increased pituitary content of MSH may be associated with inhibition of MSH release, and decreased pituitary MSH may mean an increased release of the hormone.

Melatonin, a serotonin derivative produced by the pineal gland, is the most potent agent known to lighten isolated frog skin<sup>8</sup> as well as frogs darkened by removal of the hypothalamic area<sup>9</sup>. In addition to exerting opposite effects on skin pigmentation in the frog, melatonin and MSH may also have opposite effects on the rat thyroid<sup>10,11</sup>.

The present investigations suggest a regulatory mechanism for the control of the release of pituitary MSH in the albino rat. Intravenous injection of exogenous MSH caused an elevation of the pituitary content of MSH, while injection of melatonin caused a depletion of the pituitary content of MSH. On the basis of the other studies already mentioned, it seems possible that release of MSH from rat pituitaries may be inhibited by raised concentrations of circulating MSH and perhaps stimulated by an increase in the concentrations of circulating melatonin.

In these experiments, 200 g albino Sprague-Dawley rats were anaesthetized with ether and 0.5 ml. of the test material diluted in 0.01 molar acetic acid-0.9 per cent sodium chloride was injected into the jugular vein. Twenty minutes later the rats were decapitated and their pituitaries removed. After being weighed, the pituitaries of four rats from each group were pooled, homogenized in acidified saline, and assayed for MSH activity in hypophysectomized frogs (*Rana pipiens*), as described previously<sup>12</sup>. Melatonin was initially dissolved in ethanol, the other compounds in 0.1 molar acetic acid.

The injection of highly purified natural and synthetic preparations of MSH caused a significant increase in the MSH content of the pituitaries of recipient rats as compared with the MSH levels of pituitaries of rats injected with only diluent (Tables 1-3). These increased pituitary MSH levels were related to the dose of MSH injected (Tables 1 and 2).

Possible explanations for the increased MSH content of rat pituitaries after injection of exogenous MSH include: *a*, accumulation of the exogenous MSH by the pituitary; *b*, direct feedback effect on the pituitary itself; *c*, inhibition of release of a possible hypothalamic factor stimulating MSH secretion<sup>3,13</sup>; and *d*, stimulation of release of the hypothalamic factor inhibiting MSH secretion<sup>3,4,14</sup>.

Table 1. EFFECT OF HIGHLY PURIFIED NATURAL MSH ON PITUITARY MSH CONTENT

Material	Dose/rat (mg)	Pituitary MSH (units/mg)	95 per cent confidence limits	Increment in pituitary MSH from control (units/mg)

$\alpha$ -MSH (Lerner, Lande and Upton)	0.02	2,928	2,381-3,475	+1,408
Control (acidified saline)	—	1,460	1,358-1,562	—
Control (acidified saline containing 12 per cent ethanol)	—	1,435	1,237-1,633	—
Melatonin	0.112	604	525-683	-831

The small amounts of exogenous MSH accumulated by kidney, adrenal, muscle, and liver (Table 2) make it unlikely that the increased MSH content in the pituitaries was due to a simple deposition of the injected hormone. The possibility remains, however, that the pituitary has an avidity for concentrating MSH similar to that exhibited by the thyroid for trapping iodide. MSH apparently does not exert its effect directly on the pituitary, because the pituitaries of frogs the hypothalami of which have been destroyed contain a decreased amount of MSH in spite of elevated circulating levels of MSH<sup>2</sup>.

The most probable explanation is that administration of exogenous MSH caused an increase in the levels of this hormone in the plasma which, in turn, led to inhibition of the release of pituitary MSH. The reciprocal relationship between pituitary secretion of MSH and the plasma levels of this hormone may operate by a negative feedback mechanism similar to that existing for other hormones<sup>15</sup>. The hypothalamus, the probable target site of this feedback, may then regulate pituitary secretion by elaborating a factor controlling the release of MSH. Most evidence suggests that this hypothalamic factor primarily inhibits pituitary MSH release<sup>1-5,14</sup>.

Corticotropin A also increased the MSH activity of pituitaries from recipient rats (Table 3). The intrinsic MSH activity of the corticotropin was insufficient to explain this action. Because of the similarity of certain amino-acid sequences in both MSH and corticotropin, it is possible that corticotropin affected the hypothalamic receptors for the factor controlling MSH release. The failure of dexamethasone to increase pituitary MSH content significantly (Table 3) suggests that corticotropin did not exert its effect by stimulating the adrenals. The intrinsic MSH activity of corticotropin was also insufficient to account for more than 1 per cent of the rat pituitary MSH activity<sup>2,3</sup>. Larger doses of lysine vasopressin had no significant effect on pituitary MSH content (Table 3).

Injection of melatonin caused an effect on pituitary MSH content opposite to that obtained with MSH. Table 3 shows the significantly decreased MSH content found in the rat pituitary after injection of melatonin. The possibility of accumulation of melatonin by the pituitary was not completely excluded.

The data demonstrate that injection of exogenous MSH into the circulation of the rat causes an increase in pituitary MSH content. Conversely, injection of melatonin results in a decrease in pituitary MSH content. These findings indicate that MSH and possibly melatonin may be concerned with the regulation of MSH release in a class of vertebrates in which MSH has no clearly established function. In addition, this demonstration of regulatory mechanisms of pituitary MSH release in albino rats supports the concept that MSH may have an extra-pituitary function in mammals.

We thank L. Wilkinson and S. Viosca for technical aid and Dr. E. Ferguson for help in preparing this article.

### Distribution of Cytochrome Oxidase, Monoamine Oxidase and Carbonic Anhydrase in the Carotid Body of the Rabbit

Joels and Neil<sup>1</sup> showed that a high concentration of carbon monoxide in the fluid perfusing the carotid body of a cat produced an increase in discharge rate in the carotid sinus nerve. Carbon monoxide forms an unstable complex with the iron atom in cytochrome oxidase and this is broken down by strong light; illumination of the carotid body perfused with a large concentration of carbon monoxide reduces the intensity of the discharge induced by carbon monoxide. This was interpreted by Joels and Neil<sup>1</sup> to indicate the presence of cytochrome oxidase in the carotid body. Lee and Mattenheimer<sup>2</sup>, however, found only very low cytochrome oxidase activity in the carotid body glomus tissue of slaughterhouse-killed bullocks. The distribution of monoamine oxidase is of interest in connexion with the large concentration of a catecholamine, which appears to be dopamine, in the chemoreceptor or type I glomus cells<sup>3</sup>, and the possibility of a catecholamine acting as a transmitter in this tissue as suggested by Lever and Lewis<sup>4</sup>. Carbonic anhydrase activity was found to be high in the glomus tissue by Lee and Mattenheimer<sup>2</sup>, who used a histochemical method, but they did not examine its distribution within the glomus tissue. Black, McCloskey and Torrance<sup>5</sup> showed that inhibiting carbonic anhydrase with sodium acetazolamide slowed the carbon dioxide response of the cat carotid body.

The distribution of cytochrome oxidase, monoamine oxidase and carbonic anhydrase has now been investigated in the course of other work on the rabbit's carotid body. The animals were killed by a blow on the head. The carotid bodies were removed immediately and frozen on to a microtome chuck with a carbon dioxide freezer. Sections 20 $\mu$  thick were cut in a cryostat and floated on to the incubation media for the three enzymes. In addition, six carotid bodies were perfused through the carotid artery with 2.5 per cent glutaraldehyde in 0.1 molar phosphate buffer, pH 7.4, and fixed for a total of 30 min. After 2 h of washing in buffer they were frozen on to a microtome chuck and cut in the cryostat.

Cytochrome oxidase was demonstrated on sections of fresh tissue by the method of Burstone<sup>6</sup> with *p*-aminodiphenylamine and 1-hydroxy-2-naphthoic acid or 8-amino-1,2,3,4-tetrahydroquinoline as the coupling agent. The

method of Glenner, Burtner and Brown<sup>7</sup> was used to show monoamine oxidase in unfixed tissue sections and that of Morris and Swayne<sup>8</sup> for carbonic anhydrase on sections of both fresh and fixed tissue.

Cytochrome oxidase, with 1-hydroxy-2-naphthoic acid as the coupling agent, gave a red-brown colour which faded within 1 month. The precipitate with 8-amino-1,2,3,4-tetrahydroquinoline was dark blue and did not fade noticeably over 2 months. With both agents the colour was confined to the type I glomus cells. The precipitate was granular and the granules were of the same size as the mitochondria seen in electron micrographs of type I cells. It was absent from nerve fibres and connective tissue and only faint in the smooth muscle of blood vessels. The sustentacular or type II glomus cells could not be distinguished on the surface of the type I cells.

Monoamine oxidase activity is shown by a dark blue formazan precipitate in the method used. It was found in the cytoplasm of elongated or irregular cells surrounding the groups of type I cells in a single layer. These cells with nuclei much smaller than those of the type I cells are probably type II cells. Connective tissue did not stain, but some myelinated nerve fibres showed a granular deposit.

The final reaction product of the carbonic anhydrase method is black cobalt sulphide. The groups of glomus cells were strongly stained; in fresh tissue sections the precipitate was granular and largely confined to the cytoplasm of type I cells. In the fixed material the reaction was stronger but less well localized, although it was still heaviest in the type I cells. Any red cells present stained, and a few nerve bundles as well. Connective tissues did not stain. All staining was prevented by including 5 mmolar sodium acetazolamide in the incubation medium. The enzyme appears to be localized in type I cells though results obtained with the usual methods for this enzyme have been criticized by Pearse<sup>9</sup> and by Arvy<sup>10</sup>.

### Nature of the Variation in Flower Colour in *Vicia*

From earlier work it was concluded that the principal factor concerned in promoting blueness in anthocyanin-pigmented flowers of *Lathyrus* species was the presence of flavonol co-pigments<sup>1,2</sup>. It was of interest to extend the observations into the related genus *Vicia* to determine whether a similar conclusion might be reached. In the latter genus the range of flower colour is similar to that found in *Lathyrus*. Species were selected for investigation which gave some representation of the colour range. Hydrolysed extracts of standard and wing petals were prepared and then examined by filter paper chromatography as described earlier<sup>1</sup>.

As in wild material of *Lathyrus*, the anthocyanins are glycosides of delphinidin and its related methylated derivatives petunidin and malvidin. The same flavonols, quercetin and kaempferol, are also present in the two genera. These occur as glycosides before hydrolysis.

Table 1. CONSTITUENTS OF HYDROLYSED EXTRACTS AND pH OF EXPRESSED SAP IN RELATION TO PETAL COLOUR

Species	Colour	pH	Anthocyanidins			Flavonols	
			D	P	M	Q	K
<i>V. atropurpurea</i> Desf.	S red	6.9	+	+	+	—	—
	W red	7.1	+	+	+	—	—
<i>V. dumetorum</i> L.	S bluish-red	6.7	+	+	—	+	+
	W bluish-red	6.8	+	+	—	+	+
<i>V. sepium</i> L.	S bluish-red	6.6	+	+	+	±	±
	W bluish-red	6.9	+	+	+	±	±
<i>V. sativa</i> L.	S bluish-red	6.1	—	+	+	+	+
	W red	6.0	—	+	+	—	—
<i>V. narbonensis</i> L.	S blue	6.1	—	+	+	—	+
	W blue	6.6	—	—	+	—	+
<i>V. cracca</i> L.	S blue	6.3	+	+	+	±	+
	W blue	6.4	+	+	+	±	+

D, delphinidin; P, petunidin; M, malvidin; Q, quercetin; K, kaempferol; S, standard; and W, wing petals: +, present; ±, trace; —, not detected on chromatograms at loading employed. Where more than one anthocyanidin was found, the predominant substance is indicated by +\*.

Delphinidin is the bluest of the anthocyanidins and malvidin the reddest. There is no evidence that flower colour is determined by the nature of the predominant anthocyanidin (Table 1), a conclusion also reached for *Lathyrus*<sup>1</sup>. The flavonols were found in those petals which were blue or bluish-red in colour. The situation in *V. sativa* is of particular interest because this has bicoloured flowers in which the standard petal is bluer than the wings; in those *Lathyrus* species with red/blue bicoloured flowers it is generally the wing petals which are bluer. In both *V. sativa* and the bicoloured *Lathyrus* species the flavonol content of the bluer petals is substantially greater than that of the redder petals<sup>1-3</sup>. The data reported here for *Vicia* are all consistent with the view put forward for *Lathyrus* that the flavonol glycosides act as co-pigments which modify the colour towards blue.

Determinations of the pH of cell sap expressed from petal tissue were made with a micro-electrode as described earlier<sup>1</sup>. The pH values varied according to species from 6.0 to 7.1. The data provide no evidence that blueness within the genus is promoted by higher pH, because the bluer petals tend to have lower pH's than the redder ones (Table 1).

### Taxonomic Analysis of Herbarium Material by Gas Chromatography

In the recent investigation into the taxonomy of the spicate mints, cytogenetic and biometric investigations suggested that a redefinition of the species limits is necessary (R. M. Harley, in the press). One of these species, *Mentha spicata* L., the spearmint, is of commercial importance, as are many of its hybrids. The above work indicated that this species is a segmental allopolyploid derived from the diploid species *Mentha suaveolens* Ehrh (= *M. rotundifolia* auct.) and *M. longifolia* (L.) Huds. Because of the long history of cultivation mainly by vegetative propagation, and the ease with which hybrids are formed, the origins of the many cultivated forms are obscure, and because of the great morphological variability of *M. spicata* and its hybrids, such characters are not always sufficient by themselves for correct identification.

In an attempt to throw further light on the origins of *M. spicata* and its related hybrids, we have recently begun a taxonomic survey of mint oils by gas chromatography. One of us (R. M. H.) has brought together a large collection of live mints from all parts of the world, and this, which is kept in the University Botanic Garden, forms the basis of this survey.

The apparatus used is a 'Microtech GC 2000 R' gas liquid chromatograph fitted with a hydrogen flame

ionization detector and with glass columns 3/16 in. diameter, 6 ft. long. The columns are packed with 'Chromosorb G' with 2 per cent polypropylene sebacate liquid phase. The carrier gas is nitrogen with a flow rate of 35 ml./min and the column temperature is 70° C for 1 min, which is then programmed at 2° C/min up to 170° C.

A small segment of fresh or dried leaf from the middle of the main stem is inserted into an oven which leads directly to the column. In this way, only small quantities of material are needed, and no preliminary extraction is necessary.

Initial investigations indicate that the composition and relative amounts of the different terpenes in the essential oils of each species are highly characteristic of that species. Minor differences can also be used to distinguish infra-specific taxa, and also to some extent individuals within a population. In this respect the chromatographic trace can be compared with a fingerprint. Environmental factors, at least within the limits normally encountered, seem to cause very little disturbance in relative composition of the essential oils. In order to evaluate their importance, however, we are conducting a series of experiments on clonal material.

It was soon found that the terpene content of dried material differs very little from that of fresh material taken from the same plant. To see to what extent ageing of dried material occurred, we examined a range of herbarium material of two taxa, namely *M. alopecuroides* Hull and *M. citrata* Ehrh. These were chosen because it

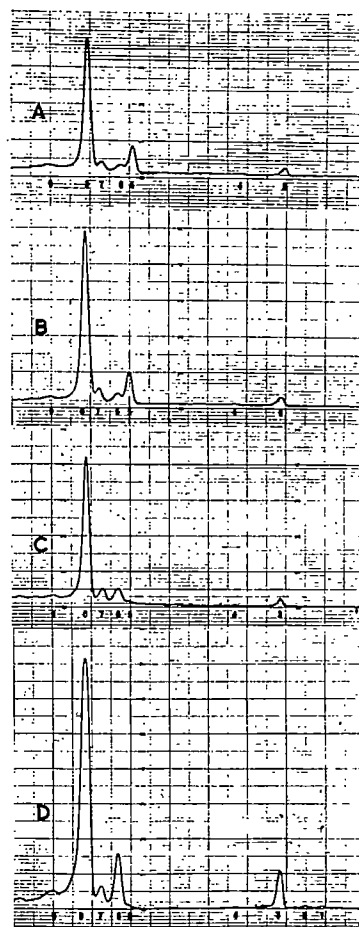

Fig. 1. Gas chromatographic traces of essential oils in herbarium specimens of *M. alopecuroides*. Each division of the chart paper represents two minutes. The peaks are numbered in order of appearance, from the right. Source of material: A, Aristotle Lane, Oxford, Leg. R. M. Harley, 1960; B, Upavon, Wiltshire, Leg. R. M. Harley, 1961; C, Essex, Leg. J. W. White, 1893; D, unlocalized, Leg. W. Sole, circa 1798.

was believed, on morphological and other grounds, that each represented a single sterile clone of hybrid origin. If this supposition were correct, any major differences in terpene content between herbarium material could be put down to ageing effects rather than genetic heterogeneity.

Both *M. alopecuroides* and *M. citrata* are widely cultivated plants which are occasionally found as garden escapes; and both are known to have been in existence for at least two hundred years.

Typical traces from four different specimens of *M. alopecuroides* are illustrated. The samples were run under identical conditions, although increased amplification was necessary in some cases, because of loss of essential oil with age. The similarity of the four traces is at once obvious. Specimens *A* and *B* (for further details see the figure) are both of recent origin and do not differ in terpene content from fresh material. They were collected in different years from different localities, and yet their traces are almost identical. The similarity is closer than that among the progeny from selfing *M. spicata*. Specimen *C* was collected in 1893 and specimen *D* in about 1798 by William Sole, although the specimen is undated. The Department of Botany at the University of Bristol is very fortunate in possessing a set of Sole's exsiccata of mints which follows the arrangement and nomenclature of his monograph *Menthae Britannicae* published in 1798.

These older specimens nevertheless have traces which are at once closely comparable with the more modern ones. Until the individual peaks have been identified, a detailed comparison is perhaps not justified, but attention is drawn to two points.

Peaks 1 and 2 are only visible on the oldest trace because of the much greater amplification. On increasing the amplification of *A*, *B* and *C*, peaks 1 and 2 at once appear. Peaks 5, 6 and 7 are clearly the least stable components on ageing, but their changes do not unduly affect the diagnostic value of the trace.

From these results, it seems very likely that *M. alopecuroides*, at least as represented by the plants so far examined, is a single clone. A similar conclusion was reached in the case of *M. citrata*, which also produced a series of almost identical traces, though much more material remains to be examined.

In the case of *M. spicata* itself we have evidence for a similar recurrence of certain clones in the material we have examined. Not only does the present technique offer considerable scope in experimental taxonomic and population investigations, but it also seems to be of value in the correct identification of old or fragmentary herbarium material, particularly where this affects typification, and where the material cannot be identified by more orthodox means. A case in point is Linnaeus' type specimen of *M. aquatica*, which may well be of hybrid origin. Gas chromatographic analysis should be able to solve this and similar problems.

One of us (M. G. B.) acknowledges the tenure of a Unilever research assistantship held during the course of this work.

### Effect of Ectopic Pituitary Grafts on the Olfactory Block to Pregnancy in Mice

THE neuro-endocrine cause of the alien male-induced pregnancy block in newly mated female mice<sup>1,2</sup> is the failure of prolactin (luteotrophic) secretion by the adenohypophysis with consequent failure of the development of the corpora lutea and the return of the females to oestrus as if mating had not occurred. Administration of exogenous prolactin<sup>1</sup> or the increased secretion of prolactin

induced by suckling in lactating females<sup>3</sup> would prevent the block in newly mated females kept near to alien males. It is now clearly established that the pheromones which cause the pregnancy block are excreted in the urine of male mice<sup>4</sup>. Hypophyseal grafts to an ectopic site are known to secrete prolactin continuously<sup>5,6</sup> and so we investigated the effects of such grafts in newly mated female mice exposed to urine from alien males.

All the females and the stud males were outbred albinos of the Parkes stock. Females were about 10 weeks old at the start of the experiment. Each intact female received a graft of the adenohypophysis from a donor female of the same age. The graft was placed in the sub-capsular space of the right kidney. The external indication of a functioning ectopic pituitary graft in the intact female mouse is the appearance of a series of pseudopregnancy-like cycles<sup>6</sup>. After two or three consecutive pseudopregnancy-like cycles in each female, shown by daily examination of a vaginal smear, they were paired with the stud male. When the vaginal plug was found (day 0), the female was separated from the stud male and housed singly. About 5–7 weeks elapsed between the grafting of the pituitary and mating of the female. Twenty-four hours after mating (day 1 of pregnancy), the female was exposed to fresh urine from twelve inbred *CBA* males, as described elsewhere<sup>4</sup>, for 3 days. A control group bearing no ectopic pituitary grafts, that is, unoperated, was mated and similarly exposed to urine from males for 3 days. Normal females were used as controls because mock operation of the females or the placing of a piece of the brain tissue in their kidney capsules in no way modified the oestrous cycles. Another group of females was mated and left undisturbed after separation from the stud male in order to assess the rate of spontaneous failure of pregnancy. Daily vaginal smears were examined from all females up to day 7 *post coitum* and a return of oestrus during this period was considered to be the external manifestation of pregnancy failure<sup>2</sup>. The results are summarized in Table 1.

Table 1. INHIBITION OF PREGNANCY BLOCK IN NEWLY MATED MICE BY ECTOPIC PITUITARY GRAFTS

Treatment	Proportion and percentage of females returning to oestrus	Proportion and percentage of females remaining pregnant or pseudo-pregnant
Urine of <i>CBA</i> males and ectopic pituitary graft	11/64 (17%)*	53/64 (83%)
Urine of <i>CBA</i> males alone	45/52 (87%)*	7/52 (13%)
Undisturbed	2/20 (10%)	18/20 (90%)

\*  $P < 0.001$

It is evident that the ectopic pituitary graft removed from neural control and hence from the olfactory influence could prevent the male-induced pregnancy block from taking place in a large proportion of newly mated females. Obviously the prolactin secreted by the pituitary graft could sustain the corpora lutea over the period when the luteotrophic activity of the female's own pituitary was temporarily suspended. Thus, the inhibition of the pregnancy block in females exposed to urine from males by ectopic pituitary graft provides additional evidence in support of the view<sup>1</sup> that the block is caused by the failure of the luteotrophic function of the anterior pituitary.

I thank Professor A. S. Parkes and Miss H. M. Bruce for suggestions and the Population Council and the Ford Foundation for financial support.

### Stridulation by a Cockroach during Courtship Behaviour

WE have found that the male of *Nauphoeta cinerea* stridulates during courtship. The male raises his wings and tegmina when courting the female, and exposes his tergum<sup>1</sup>. The female responds to a pheromone (seducin), produced in the male's abdomen, and mounts and palpates or "feeds" on his tergum<sup>2</sup>. The male initially courts without stridulating, and if the female is receptive, mating will occur quickly. If the female does not respond by mounting and feeding, however, or if she does mount and the male's attempts to grasp her genitalia are unsuccessful and she dismounts, he lowers his tegmina and wings, touches her with his antennae or legs, or stands within about 2 cm from her and stridulates. The male stridulates when the female remains quiescent; if she begins to move about he stops stridulating and usually turns facing away from her and raises his tegmina and wings.

Both adult sexes of *N. cinerea* (Olivier) have a stridulating apparatus on the pronotum (Fig. 1) and tegmina. In the male there are about forty parallel striae, each approximately  $4\mu$  apart, on the ventral surface of the latero-posterior edges of the pronotum (Fig. 2) and a row of about 400 striations, also about  $4\mu$  apart, arranged transversely down the dorso-proximal regions of the costal veins of the tegmina (Fig. 3).

Just before stridulating, the male rhythmically pumps and extends the abdomen with its tip arching upwards; as part of this co-ordinated activity the tegmina are raised and rotated slightly so that the anterior margins of the costal veins engage the ventral latero-posterior surfaces of the pronotum. The animal then begins to tremble and produces the courting sounds.

The sounds were picked up by a 1 in. Brüel and Kjaer microphone 'Model 4131', fed into and amplified by a '502A Tektronix' oscilloscope which was calibrated to register intensity. Records were stored on magnetic tape using an 'Ampex' tape deck and selected portions of the records were later filmed (Figs. 4-6) using a 'Grass C4H Kymograph' camera.

The phrase (Fig. 4) emitted by courting males begins with two to six (usually three) complex pulse trains each

having a 500 to 750 msec duration, followed by a series of disyllabic chirps, each of 60 to 80 msec duration. The terminology, with minor modification, is that of Broughton<sup>3</sup>. The phrases usually last 5-10 sec and are linked to form sentences lasting for as long as 3 min. Observations employing a dissecting microscope and stroboscope light source indicate that each pulse train is produced by a posterior, anterior, and side-to-side displacement of the pronotum over the costal veins. Chirps are produced by rapid, minute movements of the pronotum, first in a posterior, then in an anterior direction only.

We interpret the pulse train component of the courting phrase, shown in Fig. 5, to be composed of repeating units similar to the disyllabic chirps (Fig. 6). These repeating units, which precede and then follow the somewhat uniform central portion of the pulse train, probably result from lateral pivoting of the pronotal striations over the costal veins, whereas the midpulse region is the large slow posterior thrust of the pronotum observed midway in the pulse train cycle. The first syllable of a chirp appears to be made by a short, rapid, posteriorly directed displacement of the pronotum, while the second syllable results from an anterior movement. The first syllable is sharply damped.

The average sound level at the microphone placed 1 cm above the cockroach (in dB above a reference level where 0 dB =  $0.0002$  dynes/cm<sup>2</sup>) ranged from 60 to 65 dB for the pulse train peaks and from 55 to 60 dB for the chirp peaks. In a typical phrase, the pulse trains build in intensity from 55 to 65 dB, and the chirps which follow gradually decrease from 60 to about 55 dB before the next phrase begins.

An analysis of the sounds produced during courtship stridulation indicates that there is a wide frequency spectrum present in the components of the pulse train and the chirps. The audio spectrum consists of little more than a band of noise up to about 15 kc/s. This is not surprising when one considers the structure of the sound producing apparatus. The sound may be compared to that made by rubbing two finely ridged files together.

It is probable that pulse modulation of the mixed frequencies, or the rhythm of alternating pulse trains and chirps, or the rhythm of the chirps alone, provides the principal information unit, assuming the sound has meaning to the female. We have been unable to demon-

Fig. 1. *Nauphoeta cinerea* (male). Arrow points to site of the stridulating apparatus on the pronotum. Fig. 2. Part of the striae on the pronotum. Fig. 3. Part of the striae on the costal vein (magnification as in Fig. 2). Fig. 4. Oscilloscope record of a typical phrase. Time mark, 2 sec. Fig. 5. strate that the female hears or responds to the males' stridulation. Dr. R. Alexander, who has listened to our tape recordings, considers this to be a "primitive" or "simple" sound, when compared with other stridulating Orthoptera, and there is little to distinguish the cockroach sounds from those made by the plum curculio, mutillid wasp or milkweed beetle. In his view, this is a "noisy" signal, in the information sense.

A stridulating apparatus similar to that found in *N. cinerea* has been described in *Leucophaea maderae* (Fabricius), and Vosseler<sup>4</sup> claimed that this species stridulated only when captured or frightened. Like *Leucophaea*, both sexes of *N. cinerea* stridulate when held, a response called protest or reflex-cry<sup>5</sup>, or alarm or danger calls<sup>6</sup>. Recently, Dumortier suggested that sound production by the female may play a part in the maternal behaviour of certain species of ovoviparous cockroaches<sup>5</sup>.

We have found pronotal-tegmenal stridulating apparatuses in five other species of Blaberidae: *Jagrehnia gestroi* (Saussure), *Oxyhaloa buprestoides* (Saussure), *Oxyhaloa* sp. (probably *ferreti* Reiche and Fairmaire), *Henschoudeutenia flexivitta* (Walker) and *Panchlora nivea* (Linnaeus), but not in eighteen other species belonging to sub-families of Blaberidae. Species of *Gromphadorhina* produce loud hissing sounds by expelling air through the second abdominal spiracles. The males hiss during courtship or in defence of territory<sup>7,8</sup>, and the females hiss if they are disturbed when they have young under or near them<sup>9</sup>. *Panchlora* is a member of the Panchlorinae, and *Nauphoeta*, *Leucophaea*, *Oxyhaloa*, *Jagrehnia*, *Henschoudeutenia*, and *Gromphadorhina* belong to the Oxyhaloinae<sup>10</sup>.

In the Blaberoidea, specialized sound producing devices have so far been found only in the highly evolved ovoviparous Blaberidae, and two different mechanisms for sound production (stridulation and expulsion of air through the spiracles) have evolved in some members of the Oxyhaloinae. The present finding is the first report of stridulation by a cockroach during courtship.

We thank Dr. K. Roeder for his help in determining the sound frequencies, Dr. R. Alexander for audiospectrograms, and Messrs. B. Crist and D. Loomis for technical assistance.

The stridulating structures were found in museum specimens of *Jagrehnia*, *Oxyhaloa*, and *Henschoudeutenia*. We thank Dr. A. Gurney, U.S. National Museum, and Dr. K. Princis, Lund University, for the loan of, and permission to dissect, specimens of these and other genera.

poppy grows in abundance to a height of 2.5–3.5 ft. in sunny places, and blooms in June. Its flowers are 5–7 in. across and are scarlet in colour, black blotched at the base of petals and surrounded by conspicuous bracts (Fig. 1).

In July when the petals fall and the seed capsules are still immature, a juice is exuded from them by incision; it hardens when exposed in the air.

Fig. 1. *Papaver bracteatum* Lindl.

Some of this latex was dried and made into powder. To 10 g of this powder was added 30 ml. of water and the mixture was shaken gently overnight at 40° C. After filtration, the residue was twice shaken with 30 ml. of water at room temperature for 5 h and filtered. The collected filtrates were evaporated on a steam bath to a viscous state and, while still warm, an excess of anhydrous sodium carbonate was added. The contents turned into a solid which was powdered and extracted several times with a total volume of 100 ml. of warm benzene.

This was charcoaled and after evaporation of the solvent the residue was crystallized several times in absolute alcohol.

Through this method we obtained 2.6 g of pure thebaine (26 per cent of dry latex) which was identified by infra-red absorption and proton magnetic resonance spectra. Its melting point was 193° and it was not depressed by admixture with a sample of pure thebaine; its  $[\alpha]_D^{25}$  was  $-219^\circ$  ( $p=2$  in alcohol). It is noteworthy that no morphine was found in the latex of *P. bracteatum*.

In opium approximately 0.5 per cent of thebaine is present, and in the roots of *P. orientale* only a minimum amount of this alkaloid has been reported. Twenty-six per cent of thebaine in the dry latex of *P. bracteatum* Lindl. is therefore an unusually high figure.

We thank H. Golgolab and A. Zargari for their help in determining this poppy.

## GENETICS

## Blood Groups of the Chinese in Calcutta

THE purpose of this investigation was to record the distribution of A<sub>1</sub>A<sub>2</sub>BO, MN, Rh, Kell and Duffy blood groups and of ABH secretor factor and haemoglobin variants, if any, of the Chinese in Calcutta, most of whom are reported to have migrated from Canton about two or three generations ago. They live in groups and do not seem to intermingle with Indians.

\* Obtained from ABO data.

During June–December, 1965, blood specimens were collected mainly from students and teachers of three Chinese schools in Calcutta and were tested for blood group antigens like A, A<sub>1</sub>, A<sub>2</sub>, B, M, N, C, c, D, E, e, Kell (K) and Duffy (Fy<sup>a</sup>), but because of non-availability of antisera all the specimens could not be tested for every antigen. All the antisera with the exception of anti-A and anti-B were received from 'DADE' in U.S.A. Kell and Duffy antigens were determined by Coombs test, while other antigens were determined by standard methods. The specimens of saliva were examined by the method of Race and Sanger<sup>1</sup> for ABH secretor factor. Paper electrophoresis technique was used for the detection of haemoglobin variants. All the results have been summarized in Table 1.

In a sample of 566 individuals, 44.5 per cent belong to group O, 30.0 per cent to group A, 20.0 per cent to group B and 5.5 per cent to group AB. The maximum likelihood estimates of *p*, *q* and *r* for three allelomorphous genes *A*, *B* and *O* are 19.7, 13.6 and 66.7 per cent respectively. The incidence of *B* gene in China is less than 20 per cent and that of *A* gene is more than 20 per cent, in contrast to India and South Eastern Asia where *B* is generally in excess of *A* (ref. 2). The incidence of *B* in China, however, is greater than is found in Europe. It has been noted<sup>3-7</sup> that the Chinese are characterized by complete absence of A<sub>2</sub> gene, but as in the present investigation, occurrence of A<sub>2</sub> gene at a low frequency has also been reported<sup>8,9</sup>.

Among the Chinese the incidence of *M* gene is greater than that of *N* and it varies from 50.5 per cent to 63.0 per cent against 60 per cent to 70 per cent in India. The frequency of *M* gene obtained in the present investigation is 53.8 per cent while its mean value calculated by pooling the results of all workers<sup>3-6,8-11</sup> including ours is 56.9 per cent.

The gene frequencies for *D* and *d* among 474 Chinese in Calcutta are 95.4 per cent and 4.6 per cent respectively, giving 99.8 per cent Rh-positive and 0.2 per cent Rh-negative individuals. In the detailed analysis of Rh groups, the chromosome frequencies are in general agreement with those previously reported<sup>2,4-6</sup>. The Chinese differ from the Indians in having a higher frequency of *CDe* and *cDE* and a lower frequency of *cde* chromosomes.

The Duffy positive is almost universal in Chinese as observed by Miller *et al.*<sup>5</sup> and Layrisse and Arends<sup>9</sup>, while 96 per cent among 127 individuals in the present survey are

found to be Duffy positive giving approximately 80 per cent of Fy<sup>a</sup> genes. One of 132 individuals examined was found to be Kell positive. Earlier Miller *et al.*<sup>5</sup> and Sussman<sup>6</sup> reported complete absence of Kell antigen in the blood of the Chinese.

In the present survey of 555 individuals, 73 per cent were secretors and 27 per cent non-secretors; the gene frequencies for secretors and non-secretors were 48.2 per cent and 51.8 per cent respectively. As far as we know, this is the first report of the distribution of secretor factor among the Chinese. No abnormal haemoglobin was detected.

We thank Mr. P. K. Tapaswi and Mr. S. Gupta for technical assistance.

## IMMUNOLOGY

### Inhibitory Effect of Isoantibody on *in vivo* Sensitization and on the *in vitro* Cytotoxic Action of Immune Lymphocytes

KALISS was able to show that the enhancement of tumour grafts in allogeneic recipients is mediated by antibody<sup>1</sup>. Three alternative mechanisms by which antibodies might exert their effect have been postulated by Billingham *et al.*<sup>2</sup>: (1) an afferent inhibition in which antibody combined with allogeneic cells prevents antigenic determinants from reaching immunologically competent cells; (2) a central inhibition in which antibody, by direct action on lymphoid cells, prevents their sensitization; (3) an efferent inhibition in which antibody reacting with target cells protects against the cytotoxic action of immune lymphoid cells which are competing for the same antigenic receptors. Both the afferent and the central mechanisms would affect sensitization of lymphoid cells, thought to be the most important mediators of homograft rejection. Brent and Medawar<sup>3</sup> demonstrated that extracts of antigenic tissue injected into recipients treated with antiserum did not provide immunization against a subsequent skin graft. Snell *et al.*<sup>4</sup> showed that lymphoid cells from tumour allograft recipients which had been treated with antiserum were less efficient in inhibiting tumour growth than lymphoid cells from untreated recipients. Passive immunization is also known, however, to inhibit the synthesis of antibodies<sup>4-6</sup>, and experiments involving transfer of immunologically competent cells cannot critically distinguish between cellular and humoral immunity. We have therefore analysed the effect of passive immunization on "cell bound immunity" using *in vitro* methods.

Recipient C57BL mice were immunized both actively with DBA/2 tumour cell allografts, and passively with isoantiserum. The cytotoxic action of the spleen cells of the recipient mice was evaluated by counting under a microscope and/or by an *in vitro* assay of the potential of the target cell population to form clones<sup>7</sup>. Hyperimmune anti-DBA/2 isoantiserum was prepared by injecting mice of the lymphoid cell donor strain (C57BL) between six and eight times with DBA/2 mastocytoma cells. A strongly reacting serum was obtained, with an agglutination titre against DBA/2 erythrocytes of 1:64,000 and a cytotoxic titre against DBA/2 mastocytoma cells of 1:256-1:512. Indirect immune fluorescence tests using living mastocytoma cells showed the serum to be strongly active at dilutions up to 1:128.

In four experiments, 0.2 ml. volumes of the isoantiserum were injected intravenously into C57BL mice 1 h after the immunizing dose of  $30 \times 10^6$  DBA/2 mastocytoma cells. A second group of mice received the same number of mastocytoma cells only. After 8 days, the spleens of the recipient and of untreated C57BL control mice were collected. An enhancing effect on the growth of tumour cells in most of the passively immunized mice was suggested by the formation of increased amounts of ascitic fluid containing large numbers of living mastocytoma cells.

For the *in vitro* assay, an equal volume of  $2 \times 10^7$ /ml. spleen cells was mixed with  $2 \times 10^5$ /ml. target mastocytoma cells maintained as *in vitro* cultures. Separate reaction mixtures were prepared with spleen cells from the two groups of recipient mice and from untreated control mice. One millilitre of the suspension was placed in each of two Leighton tubes and cloning assays were performed after incubation at 37° C for 24 h.

As can be seen from Table 1, the *in vitro* assay revealed that the ability of lymphoid cells of passively immunized recipients to inhibit the potential of target cells to form clones was greatly reduced or abolished. That is, the development of cell bound immunity was inhibited by the passive immunization.

Fig. 1. *In vitro* inhibition of the immune lymphoid cell reaction by antiserum.  $\Delta$ , Microscopic counts of target cells after 48 h of contact with normal lymphoid cells in presence of 10 per cent isoantiserum.  $\circ$ , microscopic counts of target cells after 48 h of contact with immune lymphoid cells in presence of increasing concentrations of isoantiserum.  $\blacktriangle$ , clones formed by target cells after 24 h of contact with normal lymphoid cells in presence of 10 per cent isoantiserum;  $\bullet$ , clones formed by target cells after 24 h of contact with immune lymphoid cells in presence of increasing concentrations of isoantiserum.

The inhibiting effect of isoantibody on lymphoid sensitization was complete in experiment 30. Incomplete but still very marked inhibition was observed in the other three experiments. An inverse relationship seems to exist between the level of inhibition and the efficacy of sensitization. In the three experiments in which the control mice showed stronger sensitization of the lymphoid cells the inhibitory effect of antibody was incomplete.

The third possible mechanism of tumour enhancement concerns reactions at the target cell level. Antibodies covering antigenic sites are thought to protect target cells against the cytotoxic action of immune lymphoid cells. Möller<sup>8</sup> was able to demonstrate the progressive growth of a tumour coated *in vitro* with antitumour antibodies even in recipients which had been immunized with normal allogeneic tissue. *In vitro* experiments by Erna M. confirmed the *in vivo* results, which suggested that antibody mediated protection against the immune lymphoid cells of the host. Brondz<sup>10</sup>, however, was unable to confirm this in a similar system.

To evaluate a possible protective effect of a passive antiserum, various concentrations of the same antiserum that had been used for passive immunization (inactivated at 56° C for 30 min) were added to reaction mixtures containing  $1 \times 10^6$ /ml. target mastocytoma cells,  $1 \times 10^7$ /ml. immune lymphoid cells of recipient C57BL mice which had received a sensitizing injection of  $30 \times 10^6$  DBA/2 mastocytoma cells 8 days previously. In control suspension, spleen cells of normal C57BL mice

Table 1. EFFECT OF ACTIVE-PASSIVE IMMUNIZATION ON *in vitro* LYMPHOID SENSITIZATION: CLONES FORMED BY TARGET CELLS AFTER 24 H OF CONTACT WITH DIFFERENT LYMPHOID CELL PREPARATIONS

Exp. No.	No. of clone forming target cells after incubation for 24 h in the presence of		
	Normal cells	Immune cells	"Active-passive" immune cells
29	146,000	3,200	88,000
30	141,000	19,000	168,000
31	800,000	2,000	72,000
32	810,000	580	280,000

added to target cells either in the presence of the highest concentration (10 per cent) of antiserum used in the test or without serum. The mixtures were placed in Leighton tubes, and cloning assays and microscopic counts were performed after incubation for 24 and 48 h.

The results shown in Fig. 1 clearly demonstrate the protective effect of isoantibody on the immune lymphocyte reaction. The effect increased with the amount of antibody added, and led to an almost total inhibition of the immune lymphoid cell reaction at the highest concentration used. The presence of 10 per cent antiserum added to control suspensions containing normal spleen cells did not affect the number of target cells which could form clones.

The experiments described here have allowed us to differentiate between two distinct mechanisms of immunological enhancement. Homotransplantation and adoptive transfer experiments indirectly demonstrated (1) an afferent or central inhibitory effect of passive immunization on lymphoid cell sensitization, and (2) an efferent protective effect of antibody against the action of immune cells.

Our *in vitro* studies, allowing a critical distinction between cellular and humoral immunity, support the possible simultaneous functioning of both mechanisms by demonstrating directly that (a) passive immunization inhibits the induction of cell-bound immunity, and (b) antibody protects against the cytotoxic action of immune lymphoid cells *in vitro*.

We thank Prof. F. Fitch and Dr. J. C. Cerottini for their help and criticism.

### Comparison of Different Isoprecipitin Sera

A SERUM has been described from a polytransfused patient (C. de B.) which gave precipitate formation in gels with some but not all normal sera<sup>1,2</sup>. The isoprecipitin was subsequently shown to react with serum low density ( $\beta$ ) lipoprotein<sup>3,4</sup>. It was recognized that C. de B. antiserum exhibited more than one kind of reaction<sup>1</sup> or had more

than one specificity<sup>1,5</sup>. Further work on serum C. de B. showed that this antiserum contains at least three different antibodies (anti-a, anti-x and anti-z)<sup>7,8</sup>. Another isoprecipitin serum (L. L.) was found which contained one of the antibodies (anti-x) present also in serum C. de B.<sup>9</sup>. The present report deals with the comparison of the following human isoprecipitin sera: C. de B.<sup>1</sup>, L. L.<sup>9</sup>, E. S., Gi<sup>10</sup>, B. B.<sup>11</sup>, E. Z.<sup>12</sup>, 700 (S. L.), 928 (J. R.), 1121 (H. K.)<sup>8</sup>, 352 (J. A.), 931 (G. R.).

To compare these sera, a panel of twenty-seven normal human sera from regular blood donors and staff at the State Institute for Blood Group Serology in Stockholm was collected and kept at  $-20^{\circ}\text{C}$  until used (within 5 months of collection). Absorptions were carried out in test-tubes by mixing equal amounts of selected panel sera with the isoprecipitin sera to be absorbed and incubating the mixture overnight at  $+4^{\circ}\text{C}$ . A gel diffusion technique on microscope slides was used as described elsewhere<sup>7</sup>.

The panel sera were characterized by testing against serum C. de B. unabsorbed as well as absorbed with each of fifteen of the twenty-seven panel sera. In this way the panel sera could be divided into six groups (Table 1). The reaction patterns of the different unabsorbed isoprecipitin sera against this panel are given in Table 2.

Additional tests on other normal sera from between ten and two hundred unrelated individuals living in the Stockholm area did not reveal any difference between the reaction spectra for sera E. S., Gi, B. B., E. Z., 700 and 928 as compared with serum L. L. Absorption tests or presence of interference reactions in agar gel gave no evidence for more than one single kind of antibody molecules in these isoprecipitin sera. The above-mentioned sera are consequently assumed to be all of the specificity anti-x. Sera 1121, 352 and 931 gave the same reaction spectrum as serum C. de B. when tested unabsorbed (Table 2). After absorption of these sera with selected panel sera, differences were, however, revealed (Table 3).

The absorption data for serum 1121 can be accounted for by assuming the presence of anti- $a_1$ , +anti-x but absence of anti-z in this serum. Similarly, the absorption data for 352 can be accounted for according to the present model by assuming that 352 does have the "complex" antibody anti-xz in addition to the "simple" antibodies anti- $a_1$  and anti- $z_2$  (ref. 13). Consequently, addition to the antiserum of samples which possess the antigenic determinant z will inhibit the activity not only of the simple antibody anti-z but also (according to definitions<sup>13</sup>) of the complex antibody anti-xz whereby the antiserum will no longer react with samples having only the x and/or the z antigen.

In the same way, the absorption data for serum 931 are accounted for according to the present complex-complex model of classification by assuming the existence of the complex antibody anti-a<sub>1</sub>x in addition to the simple antibody anti-x.

Table 1. CHARACTERIZATION OF AND NOTATION FOR PANEL SERA AS DEFINED BY SERUM C. DE B. UNABSORBED AS WELL AS VARIOUSLY ABSORBED

VI	(a <sub>1</sub> -x-z-)	-	-	-	-	-	-	-

Group	Notation	352	Antibodies: anti-a <sub>1</sub> , anti-xz, anti-z					
			352 +I	352 +II	352 +III	352 +IV	352 +V	352 +VI
I	(a <sub>1</sub> +x+z+)	+	-	+	-	+	+	+
II	(a <sub>1</sub> +x+z-)	+	-	-	-	+	+	+
III	(a <sub>1</sub> +x-z+)	+	-	+	-	+	+	+
IV	(a <sub>1</sub> +x-z-)	+	-	-	-	-	+	+
V	(a <sub>1</sub> -x+z-)	+	-	-	-	+	-	+
VI	(a <sub>1</sub> -x-z-)	-	-	-	-	-	-	-

Group	Notation	931	Antibodies: anti-a <sub>1</sub> x, anti-x					
			931 +I	931 +II	931 +III	931 +IV	931 +V	931 +VI
I	(a <sub>1</sub> +x+z+)	+	-	-	+	+	-	+
II	(a <sub>1</sub> +x+z-)	+	-	-	+	+	-	+
III	(a <sub>1</sub> +x-z+)	+	-	-	-	-	-	+
IV	(a <sub>1</sub> +x-z-)	+	-	-	-	-	-	+
V	(a <sub>1</sub> -x+z-)	+	-	-	+	+	-	+
VI	(a <sub>1</sub> -x-z-)	-	-	-	-	-	-	-

Absence of (a<sub>1</sub>-x+z+) and (a<sub>1</sub>-x-z+) samples means that the possibility that additional complex antibodies with, for example, the antibody specificity anti-z are present in the antisera which are regarded as having the antibody specificity anti-a<sub>1</sub> cannot be dismissed. Thus, serum 931 may either have the additional complex antibody anti-a<sub>1</sub>xz or have this antibody instead of anti-a<sub>1</sub>x. The present model does thus only represent an attempt to account for the data in a qualitative way according to the most economic model with regard to symbols introduced and under the basic assumption that one antigenic determinant reacts with and absorbs only those antibodies which have the corresponding antibody specificity. Other models for the Ag-system based on "simple-complex", "complex-simple" or "complex-complex" notations<sup>13</sup> are thus possible and will be discussed elsewhere.

Several other isoprecipitin sera have and most probably will be discovered, and so it would be of great interest if the definition of their specificities could be co-ordinated with the present work. It is therefore suggested that small samples (about 2 ml.) should be submitted to one or the other of us for definition and comparison of their specificities.

This investigation was supported in part by U.S. Public Health Service grants from the National Cancer Institute.

## Development of Immunological Capacities in Normal and Thymectomized Mice

THE presence of thymus has been shown to be essential for the normal development of immunological capacities by a number of investigators. Antibody response and homograft immunity are the usual criteria of the immunological response. The capacity to produce antibody plaque-forming cells and thus to produce serum antibody in response to sheep erythrocyte antigen has been reported to be impaired in adult mice by neonatal thymectomy<sup>1-3</sup>. In this report the development of capacities for the production of haemolysin and homograft immunity in thymectomized mice as compared with those of sham-thymectomized control mice will be presented.

Inbred mice of strain *SL* were thymectomized or sham-thymectomized 24-36 h after birth according to the method of Sjodin *et al.*<sup>4</sup>. On days 5, 8, 13, 20, 30, 45, 60 and 120 of life, both groups of mice received a single intraperitoneal injection of 50 per cent (v/v) washed sheep erythrocyte suspension. Mice younger than 20 days of age received 0.025-0.50 ml. of the antigen suspension according to their body weights, but 0.1 ml. was injected into all the mice older than 30 days of age. More than six mice for each group were killed by bleeding after cutting the femoral vessel 4 days after injection of the antigen. Sera were stored at -25° C and were titrated together at the completion of the experiment. After inactivation, serial twofold dilutions of sera with an initial dilution of 1:40 in 0.2 ml. of magnesium saline solution were mixed with 0.2 ml. of 2 per cent sheep erythrocyte suspension. The mixtures were incubated at 37° C for 30 min after addition of guinea-pig complement. A limit dilution giving complete haemolysis was considered the titre of the serum. The method of Jerne *et al.*<sup>5</sup> was used with minor modifications<sup>1</sup> to count antibody-forming cells in the spleen. Male mice of strain *C57BL*, which differs from *SL* at the *H<sub>2</sub>* histocompatibility locus, were used as skin donors. Recipient mice of strain *SL* received skin grafts on days 15, 30 and 60 of life. The skin homografts were full-thickness circular specimens, 6 mm in diameter. They were grafted on the dorsal surface of the recipients and a pressure dressing was applied. The grafts were examined daily after day 8.

The results of haemolysin assay are shown in Fig. 1. In the thymectomized group most of the mice immunized younger than 45 days old showed the haemolysin titre less than 1:80. On the other hand, the sham-thymectomized control group immunized at 13 days old developed 1:200 of mean haemolysin titre which increased gradually with the age up to 1:2,720 at 120 days old. It is interesting that the gradual increase of antibody response was also observed in the thymectomized group. In this group the mean haemolysin titre at 120 days old was about 1:430, which approximately corresponds to the titre at 30 days old in the control group.

Fig. 1. Haemolysin titres in *SL* mice 4 days after immunization at various ages. Bars represent standard errors. O, Thymectomized mice; ●, sham-thymectomized mice.

Fig. 2. Number of antibody-forming cells in spleens 4 days after immunization at various ages. Bars represent standard errors. O, Thymectomized mice; ●, sham-thymectomized mice.

The mean numbers of antibody plaque-forming cells in both groups of mice at various ages are shown in Fig. 2. They are roughly parallel to the results of haemolysin production. In the control group, immunization at 5 days failed to elicit a detectable response, while in mice immunized at 8 days old an increase in the number of plaque-forming cells was found. Thereafter, the cell number increased rapidly at 13 days of age and then gradually up to 120 days of age. On the other hand, in the thymectomized group no appreciable plaque-forming cells could be found in mice immunized until 30 days of age, when only less than one tenth of the number of cells as compared with that of the control group were detected. After 30 days the number gradually increased up to 120 days of age.

The skin homograft survival times are shown in Table 1. In the control group, skin grafts on the mice older than 15 days of age were rejected regularly after 10–13 days of survival. In the thymectomized group mice grafted at 15 days old showed a marked prolongation of rejection time and most of them accepted the skin graft permanently. On the other hand, a considerable degree of homograft immunity was observed in mice grafted at 60 days of age; these rejected the grafts mostly within 30 days.

Table 1. SURVIVAL TIMES OF C57BL SKIN GRAFTS TRANSPLANTED TO NEONATALLY THYMECTOMIZED AND SHAM-THYMECTOMIZED SL MICE OF VARIOUS AGES

Age of recipients (days)	Survival times of skin homografts (days)	
	Sham-thymectomized	Thymectomized
15	10, 11, 12	> 60, > 60, > 60, 42
30	10, 11, 11, 12, 13, 13	> 60, > 60, > 60, 41*, 33*, 27*, 16
60	11, 11, 11, 12	58*, 27*, 22, 19, 16, 16, 11

\* Died with intact skin graft.

The present results demonstrate that in normal mice the capacity to produce haemolysin plaque-forming cells and serum haemolysin develops rapidly between 8 and 13 days after birth and then increases gradually. The full homograft immunity was already recognized 15 days after birth in normal mice. The results of the plaque-forming cell response of normal mice of various ages coincide well with those reported in the rat<sup>6</sup>. It has recently been reported that newborn mice of different strains start to respond to immunization with sheep erythrocyte at different ages between 5 and 10 days<sup>7</sup>. According to the present results the SL mice appear to begin to respond at about 8 days of age.

In neonatally thymectomized mice, it was suggested that a low rate of production of competent cells for serum antibody and homograft immunity still continues even after thymectomy, because the number of haemolysin plaque-forming cells and serum haemolysin titre increases,

and homograft immunity is restored to some extent by the age of the thymectomized mice. These results are supported by recent findings of Rogister<sup>8</sup>, which were obtained by comparison of haemagglutinin production and homograft immunity between young and adult groups of neonatally thymectomized A.S.W. mice. It will be of interest to see whether this low rate of production of competent cells is caused by the influence which the thymus had exerted before thymectomy or by the function(s) of as yet unidentified system(s).

### Cholera Toxin Neutralization and Some Cellular Sites of Immune Globulin Formation in *Cercopithecus aethiops*

As a rule, *Vibrio cholerae* does not enter the intestinal tissues and the blood stream. Cholera is a disease due to the toxins of the causative vibrio which are liberated in the lumen of the gut. The toxins have not yet been completely defined but the most important of them seem to be those of group 2 of Burrows<sup>1</sup>. These produce a cholera-like syndrome when injected into the upper part of the small intestine of infant rabbits or into the ligated intestinal loop of adult rabbits<sup>1,2</sup>. The serological responses of vervet monkeys (*Cercopithecus aethiops*) to crude cholera toxin prepared according to Oza and Dutta<sup>3</sup> and Burrows *et al.*<sup>2</sup>, phenolized cholera vaccine, and *V. cholerae* lipopolysaccharide have been investigated by our group<sup>4,5</sup>. It was found that the serum immune globulin G is the most important carrier of the *V. cholerae* toxicity neutralizing factor(s) in the circulating blood. The purpose of these experiments was to establish the antibody producing capability of mesenteric lymph gland and spleen cells, as well as to investigate the relationship of serum Ig-bound antibodies to the toxin neutralizing capability of Ig in the secretions and excretions of the intestinal tract.

Six adult vervets weighing 2 to 2.5 kg, of both sexes and of approximately the same age, were used. Two of them were immunized with the Watanabe type<sup>6,7</sup> *V. cholerae* lipopolysaccharide (LPS) prepared from El Tor strain B 17. Two injections of 1 mg each were given in six month intervals, and four animals were not immunized. Two of the latter group were challenged, together with those that received LPS, with the intracellular vibrio toxin (IC) of Burrows<sup>1,2</sup> administered through a duodenal sonde 2 weeks after completed immunization. The two unimmunized vervets served as controls. The amount of the IC used per monkey was derived from 5 to 5.4 × 10<sup>11</sup> of strain B 17 vibrios. Blood was drawn from all vervets before this operation, and all animals were bled 4 days later. Saliva was collected with the aid of plastic sponges<sup>8</sup> inserted for 30 min between the cheek and the gums of the vervets under anaesthesia. Laparotomy was performed on the same day on all six animals, under general anaesthesia. The intestines of the vervets that received IC appeared distended, engorged and contained much

liquid. Splenic biopsies were performed, and one mesenteric lymph gland near to the ileo-caecal valve was collected from each monkey. The contents of the upper jejunum were drawn into a syringe after punch enterotomy of an isolated 6 cm long loop. Gastric contents were aspirated by similar entry with a syringe into 0.07 M phosphate buffer, pH 7.8. The bleeding from the spleen was controlled by oxidized cellulose sponge application. The incisions of the jejunal and of the stomach wall were closed using inverting sutures with a continuous overlay to assure complete closure. The post-operative course was uneventful and complete in 7 days.

IgG, IgA and IgM from the sera and excreta were separated according to the method of Vaerman *et al.*<sup>8</sup>. The polysaccharide from *V. cholerae* biotype El Tor strain E 17 was absorbed on sheep red blood cells and the number of antibody producing cells in the splenic tissue and in the mesenteric lymph gland was determined by the procedure of Halliday and Webb<sup>9</sup>. IgA and IgM producing cells were suppressed by anti-A and anti-M sera to allow the enumeration of haemolysing IgG cells. On other plates, IgG and IgM were suppressed to allow the IgA forming cells to be seen. In the third experiment IgM was distinguished after addition of anti-G and anti-A sera. The cholera toxigenic activity of IC was titrated with the aid of the method of Read<sup>4,10</sup>. All tests were carried out in triplicate.

Table 1 demonstrates that all serum immune globulins increased after the challenge, while saliva contained principally IgA. This is in accordance with the observations of Tomasi *et al.*<sup>11</sup>, who found that this immune globulin predominates in the saliva. The gastric contents also revealed a preponderance of IgA. Fisher *et al.*<sup>12</sup> and Hurlimann<sup>13</sup> pointed out, however, that proteins in the gastric contents may be decomposed in spite of the neutralizing effect of the collecting fluid. More IgG was found in the upper jejunum, but the IgG : IgA ratio was lower than in the serum, a phenomenon discussed by Fisher *et al.*<sup>12</sup> for gastric disorders. Ig levels were not increased significantly in the saliva or in the gastric contents after cholera toxin administration when compared with those in unvaccinated and unchallenged animals. Higher IgG and IgA titres were found, however, in the intestinal contents of those vervets which received IC than in the control animals.

† Per 10<sup>6</sup> cells, geometric mean of 3 determinations.

‡ Collected 4 days after challenge.

Table 2 shows that the proportion of cells producing immune globulins was elevated in unvaccinated but challenged vervets, and the number of such cells was even larger in vaccinated and challenged animals. It seems that the mesenteric lymph glands contained proportionally more Ig forming cells than the spleen. Chordirker and Tomasi<sup>14</sup> and Tomasi *et al.*<sup>11</sup> showed in their experiments with other antigens that adjacent lymph nodes produce more antibody than distant accumulations of lymphoid-plasma cells, and this rule may also apply to the present experiments in which the toxic substance was administered into the area drained by the examined mesenteric lymph glands.

The neutralizing capacity of the immune globulins could not be determined in all samples because of insufficient material. Table 3 shows that elevated titres were found in the blood sera of immunized vervets, and these levels increased further after challenge. Higher values were found in challenged and unimmunized monkeys than in the controls. The toxin neutralizing capability of IgA isolated from blood serum, saliva and stomach contents was rather poor, but this capacity was marked in IgA from the jejunal contents. The cholera toxin neutralizing capability of IgG from the jejunal contents per mg globulin was greater than that of the serum IgG, supporting the theory of Chordirker and Tomasi<sup>14</sup> and Tomasi *et al.*<sup>11</sup> about the production on mucosal surfaces of different subtypes of immune globulins. In our experiments, the sera against vervet IgG, IgA and IgM were prepared against globulins separated according to Vaerman *et al.*<sup>8</sup>. While these antisera gave one single narrow precipitation band in agar gel diffusion tests, it is quite possible that some or all immune globulins consist

of 2 or more fractions with distinct immunological behaviour, but there is at present no means of separating them. The experiments reported here do not, however, exclude the possibility that some circulating immune globulins are excreted selectively into the intestinal lumen, and it is quite possible that immune globulins reacting with cholera toxins are both excreted into the lumen of the intestines and also produced locally.

It should be noted that circulating toxin could not be demonstrated in the serum on the fourth day after its administration, nor did any of the excreta and secreta investigated by us reduce the neutralizing capability of specific immune serum against cholera vibrio IC when filtrates were tested at pH 7.6 to 8.2. It must be assumed, therefore, that cholera toxin did not interfere with these investigations. Finally, there may be errors inherent in the enumeration of cells producing Ig as well as errors introduced by the need to work with relatively small amounts of immune globulins in these experiments. We hope that further refinements of the techniques and the use of larger groups of animals will allow a more thorough investigation of the phenomena observed during these preliminary investigations.

## HAEMATOLOGY

### Inhibition of Platelet Aggregation by a Sulphonic Polysaccharide

THE anticoagulant property of heparin is well known, but some of its other effects—such as lipolysis<sup>1</sup> and inhibition of platelet aggregation<sup>2-6</sup>—are less definite. Some compounds of similar structure may possess more lipolytic and anti-aggregating activity and less anticoagulant effect than heparin, and these compounds could conceivably have clinical uses. We have investigated a sulphonic polysaccharide similar to heparin (Fig. 1) in structure, which has a marked fibrinolytic action<sup>7,8</sup> and little anticoagulant effect.

The present communication is a preliminary account of the inhibition of platelet aggregation by this compound, which could be considered as an antithrombotic drug.

Platelet aggregation was measured by Born's method<sup>9</sup> with the results given as absolute and percentage values. Citrated bovine blood was used (30 ml. of 19 per cent sodium citrate added to each 1,000 ml. of blood). The citrated blood was then centrifuged at 1,500 r.p.m. for 20 min, giving a supernatant containing  $1.5 \times 10^5$ – $3 \times 10^5$  platelets/mm<sup>3</sup> and a few erythrocytes and leucocytes. Heparin (2 U/ml.) was added to the platelet rich plasma

(PRP) to prevent clotting. At this dosage platelet aggregation is not impaired<sup>10</sup>.

The PRP was incubated with the polysaccharide for 1 h at room temperature (about 20° C). The platelet aggregation was then measured by the variations of the optical density of the PRP in a spectrophotometer. The PRP was then placed in OS 1,001 tubes, with an equal amount of 0.013 molar calcium chloride and shaken with an electric agitator at 500 r.p.m. Readings were taken at 1 min intervals for 10 min.

The results are expressed in terms of absolute variations in optical density and by the index of platelet aggregation, that is, the ratio between the initial and final values of each curve obtained over 10 min, taking the initial value as 100 per cent of the optical density. This method was applied to 100 different plasmas<sup>10</sup>. The mean index of platelet aggregation was 46, with a standard deviation of 9.0, the normal limits being between 25 and 64.

Twenty-five different plasmas were investigated, each incubated with different amounts of the polysaccharide. The average of twenty-five curves of each amount was then obtained.

Table 1. MEAN AGGREGATION CURVE FROM TWENTY-FIVE PLASMAS WITH DIFFERENT DOSES OF THE SULPHONIC POLYSACCHARIDE

Time (min)	Optical density				
0	34.2	34.0	34.2	33.4	34.7
1	24.6	24.0	25.8	26.6	30.2
2	20.6	21.6	22.7	25.7	28.0
3	18.8	20.6	22.7	25.7	28.0
4	19.2	20.2	21.4	24.8	28.2
5	19.4	20.4	21.0	24.9	27.6
6	19.7	21.0	22.7	25.7	28.6
7	20.7	23.0	23.9	26.7	29.4
8	21.8	23.8	25.6	27.0	30.4
9	22.0	24.6	25.4	27.9	30.7
10	23.2	25.2	26.0	29.6	31.2
Aggregation index	54.9	59.4	62.5	74.2	79.5
Concentration of compound (mg/ml.)	0.00	0.006	0.012	0.120	0.30

Table 1 shows that as the dose of the polysaccharide increased, the ability of platelets to aggregate decreased, that is, the optical density diminished less, and the index of platelet aggregation increased. These increases correlate closely with the dose of polysaccharide used. It can be seen that with 0.12 mg/ml. plasma the index is 74, that is, the index lies outside the limits already mentioned.

It seemed to us very interesting to find a drug which is able to inhibit platelet aggregation without impairing the haemocoagulative state. This could have more interest if the drug is also capable of fibrinolysis at the same time, because the former action can be used in prophylaxis and the latter in therapy.

The polysaccharide investigated clearly inhibits platelet aggregation. This activity is present even with a dose of

Fig. 1. Comparison between the structure of the sulphonic polysaccharide (top) and that of heparin (bottom).

0.012 mg/ml. of plasma, which is lower than that used in patients (about 0.06 mg/ml. of plasma). We therefore assume that this antithrombotic activity is evident *in vivo* as well as *in vitro*.

We believe that this substance may inhibit platelet aggregation by liberating peptides from fibrinogen, and that they might be adsorbed to the platelet membrane thus altering its ability to aggregate. This effect could also result from a lipolytic activity of the compound<sup>11</sup>, modifying the lipoproteins and phospholipids of the platelet membrane.

## BIOCHEMISTRY

### Tissue Content of Citrate and Citrate-cleavage Enzyme Activity during Starvation and Refeeding

It is known that citrate, as well as being an intermediate of the tricarboxylic acid cycle, may also be involved in metabolic regulation because it increases the substrate affinity of acetyl-CoA carboxylase<sup>1</sup> and also acts as a direct inhibitor of phosphofructokinase<sup>2,3</sup>. In view of the contradictory reports concerning the concentrations of rat liver citrate in different physiological conditions it is of interest to present data on the citrate concentrations of different rat tissues during starvation and refeeding with carbohydrate. The rats used were normal adult females weighing 200–300 g which had been raised on a standard diet (Instytut Leków, Warszawa). During the refeeding period animals were maintained on a high-glucose diet<sup>4</sup>. Rats were always decapitated at 12 o'clock. Pieces of liver and whole kidneys, heart and brain were rapidly removed, in this order, and placed in a mixture of carbon dioxide and ethanol. The frozen tissue was weighed and ground in a mortar, which was precooled, with 5 per cent trichloroacetic acid, and made up to volume for citrate analysis. Citrate was estimated according to McArdle<sup>5</sup>. Before determining the concentration of citric acid, samples were heated in a boiling water bath for 10 min.

Table 1 shows the influence of starvation and refeeding with carbohydrates on the content of citrate in the brain, heart, liver and kidney of rats. It can be seen that after

Table 1. EFFECT OF FASTING AND REFEEDING WITH CARBOHYDRATE DIET ON THE CONCENTRATION OF CITRATE IN RAT TISSUES

Treatment	Liver Concentration (μmoles/100 g wet weight of tissue)	Kidney Concentration (μmoles/100 g wet weight of tissue)	Heart Concentration (μmoles/100 g wet weight of tissue)	Brain*
Normal fed	12 ± 3 (8)	19 ± 4 (12)	22 ± 8 (5)	23, 22
24-h fast	9 ± 1 (12)	27 ± 3 (11)	39 ± 10 (5)	20, 24

72-h refeed	10 ± 2 (4)	18 ± 7 (4)	18 ± 2 (4)	23, 22

The values are the mean ± S.D. The number of animals in each group is indicated in parentheses.

\* Two rats were used in each experiment.

Fig. 1. The activity of citrate-cleavage enzyme and the concentration of citrate in liver of control rats, starved rats, and rats refeed with carbohydrate. The activity of citrate-cleavage enzyme was measured spectrophotometrically with the malate dehydrogenase method of Srere<sup>12</sup>. Rates of NADH oxidation were strictly proportional to protein concentration and linear with time. The high speed supernatant fraction (37,000g for 45 min) prepared in a medium containing 150 mmolar potassium chloride was used. The results are given as mumoles oxaloacetate formed/mg liver protein/min at 37° C (●—●), and mumoles of citrate/g of liver (○—○). Normal values (N) and values obtained 48 h after starvation (0) are shown for comparison. Mean values are also given. The vertical lines represent ± S.D. Each group contained between four and fifteen animals.

starvation for 24 h the concentration of citrate in the liver is about 30 per cent lower than normal. In contrast, the concentration of citrate in heart and kidney is greater by a factor of two than the control values. A similar pattern of change was observed after 48 h of starvation for heart and kidneys, whereas the concentration of citrate in liver returned to control values. The concentration in brain tissue did not change even after starvation for 72 h, or during the refeeding period. After 24 h of refeeding with carbohydrate, the concentration of citrate in the liver became about 50 per cent greater than the control values, while the concentrations in kidney and heart tissues decreased to normal. After refeeding for 48 h the concentration of citrate in the liver dropped to control values and on the next day of refeeding was even lower than normal. The results described here are compatible with the data reported by Parmeggiani and Bowman<sup>6</sup> for concentrations of citrate in heart both in the normal state and after fasting for 48 h. Our results are different from the unpublished data quoted by Tubbs and Garland<sup>7</sup> in respect of concentration of citrate in rat liver during starvation. These authors stated that "liver citrate concentrations are doubled or trebled by starvation". Quite opposite results were obtained by Lynen *et al.*<sup>8</sup> and they showed that "the citrate level in the rat liver after 24 h fasting has sunk to 50–60 per cent of the normal values". These latter results are similar to the data presented here. The significantly different results obtained by Frohman *et al.*<sup>9</sup> may be attributable, among other factors, to the different method used to determine the concentration of citrate and also to the different procedure used in sampling.

It is suggested that concentration in the soft tissue may be related to the difference between the activity of the citrate condensing enzyme and the activity of the citrate-cleavage enzyme. From the data presented by Srere<sup>10</sup> it is found that the ratio of the activity of the citrate condensing enzyme to that of the citrate-cleavage enzyme in rat liver is about 8, whereas analogous ratios for rat kidney and heart are 48 and 112, respectively. It is therefore plausible to assume that significant changes in the activity of citrate-cleavage enzyme, which depend on the degree of carbohydrate utilization<sup>11</sup>, may be correlated with the

concentration of citrate in the liver tissue. Fig. 1 illustrates the relation between the concentration of citrate and the activity of citrate-cleavage enzymes in rat liver tissue during starvation and refeeding with a carbohydrate diet. It can be seen that the activity of citrate-cleavage enzyme decreases in the liver of starving rats and remains at the same low level during the first 16 h after refeeding with a carbohydrate diet. During this last period the concentration of citrate in the liver is increased. This is followed by the low activity of citrate-cleavage enzyme up to 16 h of refeeding. The increase observed in the concentration of citrate in the liver may have resulted from either an increase in activity of the citrate condensing enzyme and reversal of the reaction of the extra-mitochondrial isocitrate dehydrogenase, or alternatively, from persistent low activity of the citrate-cleavage enzyme. Fig. 1 reveals a reverse relation between the concentration of tissue citrate and the activity of citrate cleavage enzyme after 48 h of refeeding. A marked increase in the activity of citrate-cleavage was associated with a gradual reduction in the concentration of citrate even to less than the normal range.

### Turnover of Brain Messenger RNA

RECENT advances in molecular biology have indicated the importance of messenger RNAs which enable the nucleotide sequence of a specific DNA region to be translated into a specific protein. In mammalian brain, as in liver, such RNA templates can be operationally defined by the presence of RNA strands which help to bind ribosomes into large functional aggregates, polysomes, and by their ability to direct the incorporation of amino-acids into proteins (refs. 1 and 2, and Appel, S. H., Scott, S., and Davis, W., in preparation). The fact that environmental stimuli can alter neuronal RNA raises the question of whether brain template RNAs are sufficiently stable to persist as permanent records of environmental changes.

Recent investigations using actinomycin D give conflicting values for the apparent half-life of mammalian liver messenger RNA. Staehelin *et al.*<sup>3</sup> originally estimated the half-life to be several hours, using large doses<sup>3</sup> (5 mg/kg) and an acellular system. On the other hand, Revel and Hiatt<sup>4</sup> demonstrated that liver messenger RNAs were stable for at least 17 h. These authors contend that the results in the cell-free system are related to an indirect action of actinomycin D which reduces the number of polyribosomes present in disrupted tissue<sup>5</sup>. Furthermore, Acs *et al.*<sup>6</sup> demonstrated a direct degradative effect on cellular RNA with actinomycin D, and Honig and Rabinovitz<sup>7</sup> demonstrated that glucose could reverse the inhibition of protein synthesis which followed the inoculation of actinomycin D.

In the present investigations I used small doses of actinomycin D to inhibit the synthesis of brain messenger

RNA and, in turn, the synthesis of protein. There was no discrepancy between the results of the *in vivo* and *in vitro* methods of analysis. Outstanding was the fact that small doses (1–20 $\gamma$ ) were lethal for rats weighing 150 g in 36–72 h when the drug was inoculated intracerebrally. Intraperitoneal injections, on the other hand, had little effect on the metabolism of brain RNA presumably because of the failure to pass the blood-brain barrier. The toxicity of the drug in such small doses may well reflect compartmentalization within the brain, but it may also reflect either the sensitivity of brain tissue to the inhibition of RNA synthesis or other actions of the drug. Measurements were made of respiration on brain slices prepared from animals inoculated 12 h previously with 20 $\gamma$  of actinomycin D and compared with animals similarly inoculated with manitol (Dr. J. Lazlo kindly performed these determinations). The results were identical in the two groups. Measurements of anaerobic glycolysis, however, yielded a 30 per cent inhibition in slices from the animals treated with actinomycin D. The meaning of this observation is not clear because of the relative insignificance of this energy producing pathway in brain.

For the studies on the turnover of brain messenger RNA, Osborn-Mendel rats weighing 150 g were injected into the frontal lobes with 20 $\gamma$  (20  $\mu$ l.) of actinomycin D (solubilized with mannitol) and were compared with animals similarly injected with mannitol on its own. The animals were then killed at varying intervals after inoculation. As an index of RNA synthesis *in vivo*, animals were inoculated intracerebrally with radioactive uridine approximately 45 min before they were killed. It had been established in previous experiments that incorporation into RNA was linear for at least 60 min, and that under these conditions actinomycin D inhibited the incorporation of uridine into total brain RNA of 60, 72, 78, and 84 per cent in 1, 4, 8, and 24 h, respectively. Preliminary experiments indicated a decrease in amino-acid incorporation into protein of 70 per cent by 12 h after treatment with actinomycin D. *In vivo* studies with isotope tracer were complicated, however, by the fact that the availability of messenger RNA may not have been the rate-limiting step under the experimental conditions used. An action of actinomycin D, for example, on the availability of high energy substrate may well make diffusion of the isotope, isotope passage across cell barriers, charging of tRNA, or the assembly of amino-acyl-tRNA on ribosomes the rate-limiting step.

As a more direct evaluation two types of *in vitro* experiments were used. It was argued that following interruption of RNA synthesis the rate of protein synthesis *in vitro* would more accurately reflect the availability of messenger RNA. Brain slices were prepared from animals at varying intervals after inoculation of actinomycin D. They were incubated with Krebs-Ringer phosphate or Krebs-Ringer bicarbonate solutions and radioactive leucine and the incorporation into tissue proteins determined. As can be seen in Fig. 1, there is a decline in the ability to incorporate amino-acids which depends on the duration of *in vivo* exposure to actinomycin D, and which appears more rapidly in the subcortical regions. Furthermore, the inhibitory effect was entirely independent of the concentration of glucose present in the incubation media. As a confirmation, protein synthesis was measured in a cell-free system under conditions in which messenger RNA was limiting. Ribosomes were prepared from either the cortex or subcortex of animals killed at different periods after *in vivo* inoculation with actinomycin D. An equivalent concentration of ribosomal RNA or protein, presumably with different concentrations of messenger RNA present, was incubated with a supernatant or pH 5 fraction from control brain, and appropriate cofactors. Here, as in the brain slice experiments, a decrease in the rate of protein synthesis was noted (Fig. 2).

In both brain slice and ribosomal systems there is a more significant inhibition of protein synthesis in the subcortical

tissue suggesting a more rapid turnover for messenger RNA. This may have been related to the greater sensitivity of subcortical tissue or to the greater concentration of drug reaching the areas. Either of these possibilities would explain the striking morphological effect on the hippocampus and contiguous structures and 15 per cent greater inhibition of RNA synthesis in the subcortex than in the cortical areas after *in vivo* injections<sup>8</sup>. When actinomycin D is incubated directly with brain slices *in vitro*, however, the inhibition of RNA synthesis is only slightly increased; there is a consistent but small further increase in the inhibition of the synthesis protein in the subcortex compared with the cortex. This observation suggests the presence in subcortical tissue of a messenger RNA with a more rapid turnover than that in the cortical tissue; however, the most plausible explanation for our results is the higher concentration of drug reaching the subcortex. These data, however, are only tentative because of the low level of RNA synthesis in the brain slice preparations. The more complete inhibition of RNA synthesis in the subcortex permits a valid estimate in that region of the turnover of messenger RNA in brain as assayed by the decay in rate of protein synthesis. It is of interest that after the ability to incorporate initially declines to 25 per cent of the zero time control, no further decline is noted from 4 h to 24 h in both brain slice and cell-free systems. This would suggest that in terms of stability at least two populations of messenger RNA may exist in the subcortex: a labile fraction with a half-life of less than 4 h representing most of the template RNAs present, and another smaller population of molecules which are stable for greater than 20 h. The data also suggest a population of relatively stable molecules in the cortex with a turnover of less than 10–12 h. Because of the slower inhibition of RNA synthesis, however, presumably secondary to the lower concentration of drug, analyses of cortical messenger RNA turnover are necessarily imprecise. Furthermore, the investigations are not of sufficient duration to rule out a second more stable population of mRNAs in the cortex as seen in the subcortex.

Measurements of the turnover of RNA in the brain slices and cell-free material do not encounter the discrepancies noted in liver systems. On the other hand, these investigations do not exclude an indirect effect of

Fig. 1. At intervals after treatment with actinomycin D, rats were decapitated, their brains excised, the cortex separated from subcortex and sliced with a razor. 100 mg portions were blotted and incubated at 37° C in Krebs-Ringer phosphate buffer with dextrose and leucine-14 after gassing with oxygen. Incorporation of radioactivity into hot TCA insoluble protein was sampled at 60 min, during the linear portion of incorporation. Each point is an average of slices from three animals each performed in triplicate. There were no significant time-dependent differences in either medium or intracellular radioactive pools.

Fig. 2. Rats were decapitated at intervals after treatment with 20 $\mu$ g actinomycin D, the brains excised, the cortex separated from subcortex, suspended in 0.25 molar sucrose containing 0.005 molar magnesium chloride, 0.025 molar potassium chloride, 0.05 moles tris Cl pH 7.6 and homogenized in a loose glass homogenizer. After centrifugation at 10,000 g for 10 min and 20,000g for 20 min, the supernatant solution was made 0.9 per cent in sodium deoxycholate and spun through a 0.5 molar sucrose/2.0 molar sucrose gradient containing the above salts at 105,000g for 2 h. The clear pellet was used as the source of ribosomes. Other additions to the incubation consisted of a supernatant fraction prepared from uninjected animals, ATP, and ATP generating system, GTP, ammonium chloride and leucine-14C. The incorporation of radioactivity into protein insoluble in hot trichloroacetic acid was linear for at least 30 min. The points on the graph represent the averages of incorporation at 20 min with ribosomal preparations from four animals; each experiment was performed in triplicate. For the zero time point the animals were injected with actinomycin D and immediately killed.

actinomycin D on the breakdown of messenger RNA, independent of its inhibiting nucleic acid synthesis. In these circumstances our data may reflect faster rates for turnover than would obtain under most physiological situations.

The presence of both labile and stable brain messenger RNA moieties would confer significant adaptive value allowing shifts in certain aspects of the metabolic expression of the cell while other aspects remained stable. It is tempting to speculate that either the labile or stable components may affect intercellular communication and synaptic activity. In these circumstances stability of information may be determined by both quantitative and qualitative features of neuronal activation and may depend on the half-life of the mRNAs involved as well as on the configurational changes and half-lives of enzymes which catalyse the interneuronal metabolic processes.

### Glucosamine Acetoacetate Condensate: a New Anti-Alloxan-Diabetes Factor

"It has been postulated that a gradual accumulation of ketone bodies in the system might be responsible for the onset of hyperglycemia and that the rise of blood sugar might be due not only to overproduction or nonutilization of glucose but, also, to a natural mechanism to combine

with some toxic metabolites in the system.<sup>11</sup> It has been proposed that the condensation product of glucose and acetoacetate (furoate condensate) prevents alloxan diabetes even when the product is in very low concentration, and that this condensation product is formed in the urine of normal people and not in those of diabetic patients<sup>2</sup>. A new route of glucose utilization and ketolysis is suggested, therefore<sup>3</sup>.

The condensation product of D-glucosamine and acetoacetate, ethyl 2-methyl-5-(D-arabinotetrahydroxybutyl)-3-pyrrolecarboxylate (pyrrole condensate)<sup>4</sup> could be involved in the biological phenomenon of antiketogenesis or ketolysis and the prevention of experimental diabetes, such as that produced by alloxan. The occurrence of the condensation product of glucosamine and acetoacetate *in vitro*, without the need of catalysis as needed in the formation of furoate condensate, suggested that perhaps the pyrrole condensates may be of importance as an antidiabetogenic factor.

Our results indicated that the 10 per cent ferric chloride test alone on urine as described by Nath and Sahu<sup>5</sup> is not sufficiently specific for use as a criterion for detecting the presence of furoate condensate. Of fifty-two diabetic urine samples tested, 27 per cent showed positive or any colour formation, and of thirteen normal urine samples 23 per cent showed any positive colour formation. As described by Nath, only normal urine gave a positive ferric chloride test indicating the presence of a furoate. Further, our paper electrophoretic investigations of normal and diabetic urine using Beckman model R at pH 7.4 of phosphate buffer followed by elution with 95 per cent ethyl alcohol and thin-layer chromatography (Eastman chromogram silica gel with butanol-acetic acid-water solvent, 4:1:5) showed that out of sixteen diabetic urines six showed pyrrole condensate and thirteen showed furoate condensates. Out of ten normal urine samples tested five showed the presence of furoate. The furoate condensate showed a characteristic dark blue fluorescence with an  $R_F$  value of 0.90 and ultra-violet wavelength 2840 Å and the pyrrole condensate shows a characteristic light blue fluorescence at the same wavelength and with an  $R_F$  value of 0.83.

Our data indicated the presence of furoate condensate both in normal and diabetic urine and the pyrrole condensate only in diabetic urine. This finding is further substantiated by our urine hydrolysis experiments<sup>6</sup> which show an increase, up to 100 per cent in five samples of diabetic urine, of glucosamine content after hydrochloric acid hydrolysis without any increase noted in the normal urine sample (Fig. 1).

Fig. 1. Average value of experimental data versus concentration.

The role of pyrrole condensates in experimental diabetes was investigated using white rats weighing 250–300 g, which have received approximately 300 mg of alloxan/kg of body weight simultaneously with pyrrole or from 30 min to 1 h afterwards. The results are shown in Table 1.

We conclude that the glucosamine-acetoacetate condensate was capable of preventing alloxan diabetes symptoms in approximately 86 per cent of the rats challenged with alloxan. The manner by which alloxan diabetes is prevented is not demonstrated except that liver glycogen<sup>8</sup> depletion which occurs in rats treated with alloxan was completely inhibited, possibly indicating that the pyrrole condensate is involved in experimental diabetes as a glycogenic factor, and that its presence in human diabetic urine suggests some role as an antidiabetogenic metabolite.

## Chondroitin Sulphate and Collagen in Inherited Skeletal Defects of Chickens

MUTANT chickens and chick embryos with well characterized hereditary defects of the skeleton<sup>1,2</sup> were obtained from the breeding flocks of the Agricultural Experimental Station of the University of Connecticut by kind permission of Drs. W. Landauer and L. Pierro.

Creepers, heterozygous for the dominant micromelia to which the breed owes its name, and normal siblings 12 weeks old were compared by methods described elsewhere<sup>3</sup> with respect to the composition of sternum cartilage and long bones in each sex. No differences in the content and type of chondroitin sulphate or in the content of collagen were found. Bones contained only chondroitin sulphate A, while the acid mucopolysaccharides of cartilage consisted of a mixture of 80 per cent chondroitin sulphate A and 20 per cent chondroitin sulphate C.

Three types of micromelic chick embryos, each homozygous for a recessive lethal mutation, were compared with normal siblings at the age of 17 days with reference to concentrations of acid mucopolysaccharides in sternum

cartilage and limb cartilage. Tissues from between thirty and sixty embryos of each type were pooled. No differences were found for the micromelia characteristic of the crooked-neck dwarf mutant or for that of Lamoreux's chondrodystrophy. In both instances, the acid mucopolysaccharides of cartilage consisted of about 60 per cent chondroitin sulphate A, 30 per cent chondroitin sulphate C and 10 per cent repeating periods of chondroitin sulphate lacking sulphate, and this was true for the mutant embryos as well as for their normal sibs. Cartilage of nanomelic embryos<sup>2</sup>, however, contained only about 10 per cent of the normal amount of chondroitin sulphate, a difference from normal easily demonstrated histologically by staining with toluidine blue. An investigation of this material was therefore undertaken in greater detail.

Various tissues were obtained from two groups of between thirty and forty nanomelic and normal embryos. Acid mucopolysaccharides were isolated and fractionated with cetyl pyridinium chloride and on 'Dowex 1x2' resin columns. The results in Table 1 indicate that nanomelic cartilage contains about a tenth of the chondroitin sulphate of normal cartilage, while a smaller reduction occurs in bone. Concentrations of collagen are comparable in cartilage but seem to be greater in nanomelic bone, possibly as a result of decreased mineralization. The purified chondroitin sulphate preparations from nanomelic and normal limb cartilage are similar in electrophoretic mobilities with near equimolar sulphate and galactosamine contents and have identical intrinsic viscosities of  $0.39 \pm 0.02$ . The principal residual amino-acid of chondroitin sulphate is serine in molar ratio to galactosamine of 0.020 and 0.026, respectively, for the nanomelic and the normal preparation.

Nanomelic skin has an essentially normal content of acid mucopolysaccharides. Similarly, nanomelic vitreous humour does not differ from normal in contents of total glucosamine and total galactosamine, which were 0.21 and 0.12  $\mu$ moles/ml., respectively.

Polymeric acid mucopolysaccharides could not be isolated from allantoic fluids of normal or nanomelic embryos. The normal and nanomelic fluids (about 2 ml. for each embryo) contained 1.44 mg/ml. and 1.58 mg/ml. of total hexosamine, respectively, divided almost equally between glucosamine and galactosamine; sulphate was less than 0.1 mole/mole hexosamine in both fluids. Because excretion of breakdown products in the allantoic fluid was not detected, it seems unlikely that the reduced content of chondroitin sulphate in nanomelic cartilage arises from the greater breakdown of the macromolecule.

We may therefore tentatively assume that a mechanism of synthesis is defective. The apparently normal rates of biosynthesis of glucosamine and galactosamine in tissues other than skeletal would presumably rule out a systemic deficiency of remote biosynthetic precursors such as glucose<sup>4</sup>. Furthermore, the local nutritional environment is unlikely to play an important part because the concentration of chondroitin sulphate is lower than normal at all skeletal sites. The simultaneous, almost normal concentrations of collagen (measured by hydroxyproline)

indicate the specificity of the effect on biosynthesis of the polysaccharide because normal, embryonic chick chondrocytes apparently produce chondroitin sulphate and collagen at the same time<sup>5-7</sup>.

It is necessary, however, to account for the apparently normal metabolism of chondroitin sulphate in nanomelic skin. In normal embryonic and adult chick cartilage, chondroitin sulphate chains are covalently linked as side chains to serine residues (unpublished observations) of an extended polypeptide backbone to yield a large macromolecule<sup>8,9</sup>. It is probable that chondroitin sulphate of embryonic chick skin is similarly linked to a polypeptide backbone. First, it can be assumed that the polypeptide backbones of chondroitin sulphate-polypeptide molecules of skin and cartilage, respectively, are different, and that mutation has affected a structural gene coding for the specific polypeptide in cartilage. Then, because synthesis of chondroitin sulphate depends on previous synthesis of a polypeptide<sup>10,11</sup>, production of a defective acceptor polypeptide results in restricted formation of polysaccharide chains.

Alternatively, if the molecular structure of the chondroitin sulphate-polypeptide is determined by identical structural genes in both tissues, then the inherited defect appearing only in chondrocytes may be in the genetic regulatory apparatus which controls the biosynthesis of the macromolecule in this type of cell. A defective enzyme for a reaction rate-limiting only in cartilage, however, is not excluded.

## PATHOLOGY

### Effects of Tobacco Smoke on Lung Tissue as measured by Electron Spin Resonance

THE presence of free radicals in tobacco smoke has been reported already. During the course of a programme concerned with free radicals and alkylating agents in tobacco smoke it was observed that the concentration of free radicals in tobacco smoke condensate varied considerably as a function of methods used for collecting and subsequent treatment with solvents. To determine the biological effects of free radicals it became apparent that a method was needed whereby smoke could be directly applied to lung tissue without first collecting and processing the condensate. The method reported here enabled lung tissue to be directly exposed to cigarette smoke in a manner similar to normal smoking and resulted in the observation of distinct changes in the lung tissue as measured by electron spin resonance (ESR).

\* Dry-weight basis. GluN, glucosamine; GalN, galactosamine; CS, chondroitin sulphate.

† 0.090 per cent GluN of normal skin and 0.070 per cent GluN of nanomelic skin isolated as sodium hyaluronate.

‡ In both normal and nanomelic skins, about a third of the CS is chondroitin sulphate B; the remainder is a mixture of chondroitin sulphates A and C.

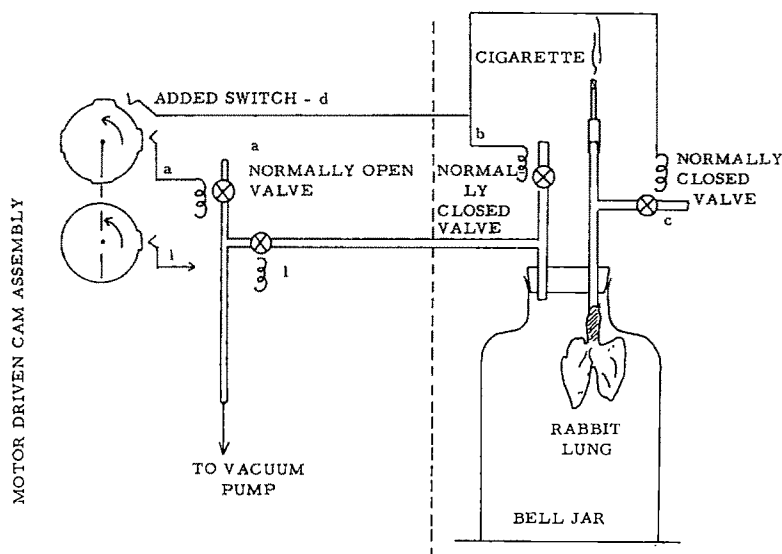

Fig. 1. Smoking apparatus.

Large adult rabbits of unknown strain and obtained locally were used. Each animal was killed by cervical dislocation and the lungs and trachea were excised intact as rapidly as possible. This was carried out within 10 min of death. The trachea was then attached to the apparatus shown in Fig. 1 using thin twine to hold it in place. The smoking apparatus (Fig. 1) consists of a bell jar, valving, and a Phipps and Bird smoking machine that was modified to exhaust the bell jar partially, hold it in the exhausted state, and then admit atmospheric air into the jar. The timing of the cycle is controlled by the cam and motor arrangement contained in the smoking machine. The smoking parameters used were: puff frequency, 30 sec; puff duration, 2 sec; inhalation time, 4 sec; butt length, 15 mm. The puff volume varied with the capacity of the lungs during each experiment. The volume was adjusted so that the lungs would fully inflate without rupturing. During the initial phases of this work several lungs did rupture, thereby allowing smoke to enter the bell jar. This was later prevented by first using the minimal puff volume that would inflate the lungs and step-wise increasing the volume until the lungs would inflate with a turgid appearance. King size, non-filtered cigarettes, manufactured in the United States, were used. The cigarettes were not preconditioned before use. They were inserted into a holder composed of rubber tubing and were

ignited by means of a lit cigarette of the same brand. A total of six cigarettes were smoked into the lungs for each experiment.

As soon as the smoking was completed the lungs were removed from the apparatus and homogenized at room temperature for 30 sec in an 'Omnimixer'. A cylindrical sample of the homogenate was then prepared and placed into a Varian liquid nitrogen dewar. Electron spin resonance spectra of the sample were then recorded at 77° K using a Varian '4500 X' band spectrometer using 100 kc/s modulation. A typical spectrum is shown in Fig. 2 together with the spectrum obtained from an unsmoked lung using the same instrument parameters and sample size. The observed spectrum was reasonably reproducible, although small changes in the relative magnitudes of the three line pattern superimposed on the broad resonance line were noted from sample to sample indicating that the observed pattern is composite. A considerable amount of additional data is required before we can

hope to arrive at any definite conclusions about the species giving rise to the signal. The similar pattern that Swartz observed in irradiated blood suggests, however, that the observed spectrum could be produced by the interaction of the free radicals in tobacco smoke with the red blood cells. This is being further investigated on lung experiments and on a series of model systems including metal porphyrin complexes. In Fig. 3 we have included the

Fig. 2. A, ESR of lung which has smoked six cigarettes; B, ESR of control.

Fig. 3. A, ESR of vacuum dried smoked lung at 77° K; ESR of vacuum dried lung at room temperature.

spectrum obtained from freeze dried lung tissue exposed to smoke. Fig. 3A represents the spectrum obtained at 77° K and Fig. 3B the same sample run at room temperature. The room temperature signal consists of a single narrow line which is typical of the electron spin resonance signal obtained from tobacco smoke condensate. On refreezing to 77° K the electron spin resonance signal observed reverts to that shown in Fig. 3A.

It is apparent from this work that the smoking system that is reported has proved to be a reliable method for exposing intact lung tissue to fresh cigarette smoke comparable with the manner of human exposure. The results are not biased by changes in the smoke that occur as a result of trapping and processing. We cannot at this time be certain of the origin of our observed electron spin resonance signal. The similarity of it to that observed by Swartz on irradiation of red blood cells causes us to anticipate that both his and our results can be explained by the formation of a covalent hexacoordinated ferric haemoglobin complex formed because of the interaction of certain molecules found in tobacco smoke or molecules formed by irradiation damage, with the haemoglobin molecule in which the bonding is normally ionic in nature. Further work is being conducted to establish this point.

### Carbon Tetrachloride Effect on Liver Autotransplants with Totally Reversed Blood Flow

LOCALIZATION of injury to specific zones in the liver lobule after the administration of many toxins is well recognized<sup>1</sup>. Carbon tetrachloride, an agent extensively examined in hepatotoxicology, characteristically produces centrilobular necrosis and lipid accumulation. Himsworth<sup>2</sup> and, more recently, Brody<sup>3</sup> suggested that the centrilobular location of injury after acute carbon tetrachloride intoxication resulted from centrilobular ischaemia secondary to the hydrocarbon's effect (directly or indirectly) on blood passing from the periphery to the centre of the lobule. This concept has been challenged on several grounds including the observation that the earliest signs of parenchymal cell injury precede vascular changes associated with ischaemia<sup>4</sup>. Several investigations have indicated that hepatic cells within different zones of the lobule have dissimilar function<sup>5</sup>. This has been ascribed to the relation of the hepatic cell to the blood flow through the lobule which causes these cells to adopt particular functions in accordance with available substrates or metabolites in the blood. Wilson describes certain zonal functions as representing habitual patterns of activity which become characteristic of hepatocytes in a particular location<sup>6</sup>. Zonal heterogeneity of function may explain the centrilobular location of acute carbon tetrachloride injury if it is assumed that hepatocytes in this location are susceptible to its effect.

Both the vascular and metabolic explanations of the zonal nature of the carbon tetrachloride lesion are related to the direction of the blood flow in the liver lobule, and so an experiment was designed to observe the effects on liver tissue of acute carbon tetrachloride poisoning in conditions of total blood flow reversal in the liver. A preliminary report of this work has been presented elsewhere<sup>7</sup>.

In mongrel dogs of both sexes (9.8–14.7 kg body weight),

the left lateral and left central lobes of the liver were removed. The left central lobe was utilized for baseline histological tissue sections. The left lateral lobe (about 25 per cent of the entire liver) was transplanted to the right side of the neck after ligation of the lobar bile duct and hepatic artery. The details of the grafting technique are given elsewhere<sup>7</sup>, and only a general description is given here. In "straight" blood flow liver autografts, transplantation was achieved by anastomosis of the lobar portal vein to the cephalic end of the carotid artery and the hepatic vein to the jugular vein. "Reverse" blood flow grafts were constructed by anastomosis of the carotid artery to the lobar hepatic vein and the portal vein to the jugular vein. Both anastomoses were end-to-end. The period of graft ischaemia was about 30 min. Arterial blood entered the cephalic segment of the carotid artery through collateral channels and blood flow and pressure (about 70 per cent of normal mean arterial pressure) were less than in the proximal segment. The hepatic artery of the graft was ligatured, and so the entire source of blood supply was thus arterialized blood at reduced pressure. "Straight" blood flow grafts served as controls for observations on the "reverse" blood flow transplants. One to twenty-three days after the grafts were established, each animal was injected intramuscularly with a single dose of carbon tetrachloride (0.5 ml. of carbon tetrachloride mixed with 0.5 ml. of sesame oil/kg body weight). Twenty-four hours after this injection, the animals were re-anaesthetized with pentobarbital and the grafts and non-transplanted livers were removed. There were twelve animals with "straight" and eleven with "reverse" blood flow grafts.

Tissue sections stained with haematoxylin and eosin and frozen sections stained with sudan IV obtained from grafted and non-transplanted liver were examined. The non-transplanted liver showed the typical changes reported at 24 h after acute carbon tetrachloride intoxication. Centrilobular necrosis was seen in all sections. The central hepatocytes adjacent to the zone of necrosis were filled with lipid droplets. "Straight" blood flow autografts exhibited the same general pattern of injury—central necrosis and lipid accumulation. Fig. 1 shows a portal tract in a "straight" flow graft surrounded by relatively normal looking hepatocytes. Lipid filled cells and necrotic areas are located beyond the periportal site. The amount of fatty deposition in these grafts appeared to be less than in the corresponding non-transplanted liver. Varying degrees of lobular atrophy, particularly centrilobular, with sinusoidal dilation were seen in these grafts. These changes resembled those seen in "straight" blood flow liver autografts without administration of carbon tetrachloride and consequently appeared to be the sequelae of the grafting procedure *per se*.

Fig. 1.  $\times 104$ .

Fig. 2.  $\times 104$ .

"Reverse" flow autografts showed the same pattern of central necrosis and lipid accumulation as the "straight" blood flow transplants and the untransplanted livers after administration of carbon tetrachloride. Fig. 2 shows a typical portal area in a "reverse" flow graft with the cells immediately adjacent appearing normal. Outside this zone, hepatocytes show marked lipid accumulation. As in the "straight" flow grafts, these changes were present together with alterations usually seen in "reverse" flow autografts. Parenchymal atrophy with centrilobular preponderance is more pronounced in "reverse" flow than in "straight" flow autografts. Where depletion and injury of parenchymal cells was extensive, collars or normal looking hepatocytes could usually be discerned in the periportal areas after treatment with carbon tetrachloride in both types of grafts. The atrophic changes attributable to the grafting procedure progressed with the age of the transplant. Consequently, the most clear-cut demonstration of persisting carbon tetrachloride effect was seen in the early grafts. In the grafts observed at 21–24 days, however, the general pattern of injury described still prevailed in both types of transplants.

This experiment suggests that carbon tetrachloride produces an effect in liver autotransplants which is comparable with that seen in otherwise normal liver. The amount of lipid in these grafts may be less than in non-transplanted liver. The amount of lipid, however, appears to be greater than that initially present in the graft. The same lobular zone lesion is produced in non-transplanted liver and in autografted liver with "straight" or totally "reversed" blood flow. It is noteworthy that R. W. Brauer commented at the NATO Symposium that, on the basis of unpublished work in his laboratory, the zone of necrosis from chlorinated hydrocarbons was the same in perfused *in vitro* rat liver preparation regardless of the direction of flow<sup>9</sup>.

Our investigation presents additional evidence against the contention that carbon tetrachloride effect on the liver is a result of ischaemia. In this experiment, centrilobular zones which received well oxygenated blood first still showed the typical response after administration of carbon tetrachloride. While the zonal pattern of acute carbon tetrachloride intoxication may result from the most susceptible cells being present in the area about the central vein, this zonal susceptibility tends to persist despite reversal of the direction of lobular blood flow in the time span investigated. Consequently, if lobular zone heterogeneity of function is the explanation for the specific site of the carbon tetrachloride lesion, and if this heterogeneity is a cellular adaptation to the direction of blood flow, then it must be assumed that cell function becomes relatively fixed despite later alteration of blood flow.

### Effect of Bursectomy on the Rous Virus Tumour Induction in Chickens

NEONATAL thymectomy has a pronounced inhibiting or stimulating effect on the growth of tumours induced by various oncogenic viruses<sup>1–12</sup>. Our task was to investigate the role of thymus in the induction of Rous virus tumours. The interest of such experiments is that there are two organs in the chickens (thymus and bursa Fabricius), one of which has the functions of a mammalian thymus.

It is well known that the function of these organs is different<sup>10,13–16</sup>. This communication concerns the role of bursa Fabricius on the induction of Rous virus tumours and on tumour growth. For this purpose the chickens were bursectomized during the first 48 h of their life. As controls I used intact or sham-operated chickens which hatched on the same day as the experimental ones. The experimental and control birds were simultaneously inoculated with the Rous sarcoma virus (strain Carr) at the age of 14–76 days. As a source of the Rous virus I used a cell-free Rous sarcoma extract, which was stored in a frozen state (at  $-70^{\circ}\text{C}$ ) for 7 months. The virus titre, which was estimated by means of virus injection to 1-day-old chickens, was  $1 \times 10^7$  LD<sub>50</sub>/ml. All experiments were made with the same pool of tumour extract. The inoculated bursectomized and control birds were observed for a period of 1.5 month after virus injection. During this period we palpated the tumours every 2–3 days and autopsied every dead chicken. All birds which remained alive to the end of the experiment were killed and autopsied. The results of the experiments are given in Tables 1 and 2.

The results of these experiments showed that the incidence of tumours in the bursectomized chickens was somewhat lower as compared with the control birds. The observed difference, however, was not large (the difference

$10^{-7}$	12	0 (0 per cent)		11	0 (0 per cent)	

between log  $LD_{50}$  in both groups was  $< 1$ ). When the bursectomized and control chickens were inoculated with the virus at the age of 14 days, the difference in incidence of tumours was still lower. There was no difference in the duration of the latent period, tumour growth rate and incidence of metastasis in bursectomized and control birds inoculated with the Rous sarcoma virus at the age of 14–76 days. Thus, bursectomy had no significant effect on the Rous sarcoma virus induction and tumour growth rate. It was known that bursa Fabricius played a principal part in regulation of the humoral antibody production in birds. Therefore, our results gave further support to the conception that the humoral antibodies did not take any important part in the immune reaction against the new cell antigen, which was induced in the host cells transformed by the oncogenic viruses.

### Adrenal Cortical Control of the Appearance of Rat Slow Alpha<sub>2</sub>-globulin

We have previously shown<sup>1</sup> that the appearance of slow alpha<sub>2</sub>-globulin among the blood serum proteins of the rat after the administration of the lipopolysaccharide (endotoxin) of *Salmonella abortus equi* is prevented by adrenalectomy. The slow alpha<sub>2</sub>-globulin response to this agent can be restored in the adrenalectomized rat by the administration of corticosterone. We wish to demonstrate that this adrenal cortical control is complete when certain other provoking agents or situations are used, but that the control is not complete when the provoking situation is immediately post-partum.

Three situations known to provoke the appearance of slow alpha<sub>2</sub>-globulin were used: partial hepatectomy<sup>2,3</sup>, growth of an implanted neoplasm<sup>4–7</sup>, and the immediate post-partum state of both mother and young<sup>4,8–9</sup>. In each situation, three experimental conditions were used: (a) the normal animal was placed in the desired situation; (b) the adrenalectomized animal was placed in the same situation; and (c) the adrenalectomized animal was placed in the situation but was given corticosterone as replacement therapy. The general procedures, including vertical starch gel electrophoresis, and the rats used have been described previously<sup>8</sup>.

Adrenalectomies were carried out as before<sup>1</sup> and all adrenalectomized rats were given 1 per cent sodium chloride instead of drinking water. Partial hepatectomies were performed by a modification<sup>2</sup> of the method of Higgins and Anderson<sup>10</sup>. If partial hepatectomy and adrenalectomy were to be combined, the former was performed 21 days after the latter. Replacement therapy consisted of the subcutaneous administration of 1 mg of corticosterone twice daily from the day before hepatec-

tomy until the second day after this operation; at this time the blood samples were taken.

Dorsal subcutaneous implantations of the Walker 256 carcinosarcoma were used to produce a growing neoplasm. In the appropriate animals, adrenalectomy was performed 2 days before the neoplasm was implanted. Blood samples were taken between 15 and 19 days after implantation of the carcinosarcoma, depending on the growth rate of the malignancy. Replacement therapy again consisted of 1 mg of corticosterone administered twice daily, beginning on the eleventh day after tumour implantation and lasting until the day when the blood sample was taken.

In the post-partum situation, blood samples were taken for analysis from both mother and newborn on the second day after birth. For each analysis, blood from at least three young of the same litter was pooled. Adrenalectomies were here performed on the second day of pregnancy (the day of the appearance of sperm in the vagina is counted as the first day). Preliminary experiments had shown that the administration of 1 mg of corticosterone twice a day caused many abortions or neonatal death, and so only 0.5 mg of corticosterone was given twice daily, beginning on the nineteenth day of pregnancy. The young of adrenalectomized mothers tended to be considerably smaller than those of untreated mothers.

The results obtained are summarized in Table 1. It will be seen that, when either partial hepatectomy or a growing neoplasm constitutes the stimulus used to provoke the appearance of slow alpha<sub>2</sub>-globulin, control is exercised by the adrenal cortex in the same manner as when a bacterial lipopolysaccharide was previously used. Further, the loss of response to these provoking agents in the adrenalectomized animal can again be reversed by the administration of corticosterone. A similar sequence of events has been reported when turpentine inflammation was used as the provoking agent<sup>11</sup>. The adrenal cortical control over the appearance of slow alpha<sub>2</sub>-globulin, therefore, seems to exist for a wide variety of provoking agents.

The data of Table 1 further show, however, that, in the case of the post-partum animals, the adrenal cortical control is not as strong as in the other situations, because slow alpha<sub>2</sub>-globulin will generally be present in the blood serum of a rat 2 days after the birth of a litter whether or not the animal is adrenalectomized. Slow alpha<sub>2</sub>-globulin is present in the young regardless of the adrenal status of the mother. The observation that the incidence of slow alpha<sub>2</sub>-globulins in the adrenalectomized mothers is only 57 per cent whereas in adrenalectomized and corticosterone treated animals it is 100 per cent can be regarded as evidence that adrenal cortical control is effective in the post-partum situation but incomplete, that is, factors other than the activity of the adrenal cortex substitute, at least in part, for the activity of the adrenal cortex. It can be suggested that the elevated concentrations of steroid hormone associated with pregnancy and lactation are involved here.

Table 1. ADRENAL CORTICAL CONTROL OF THE APPEARANCE OF SLOW ALPHA<sub>2</sub>-GLOBULIN

Test situation	Adrenal-ectomy	Replacement therapy (corticosterone)	No. of rats	Percentage of samples showing slow alpha <sub>2</sub> -globulin
Hepatectomy	No	No	8	100
Hepatectomy	Yes	No	9	0
Hepatectomy	Yes	Yes	8	75
Neoplasm	No	No	20	95
Neoplasm	Yes	No	13	0
Neoplasm	Yes	Yes	7	86
Post-partum, mother	No	No	20	80
Post-partum, young	No	No	22†	100
Post-partum, mother	Yes*	No	14	57
Post-partum, young	Yes*	No	8‡	100
Post-partum, mother	Yes*	Yes†	5	100
Post-partum, young	Yes*	Yes†	5‡	100

\* Mother only adrenalectomized.

† Mother only given replacement therapy.

‡ Number of pools of young.

The following conclusions can be drawn. (1) Adrenalectomy prevents the appearance of slow  $\alpha_2$ -globulin in a series of diverse situations in which this globulin normally appears. (2) The effect of adrenalectomy with respect to the appearance of slow  $\alpha_2$ -globulin can be reversed by the administration of corticosterone in all cases investigated. (3) The adrenal cortical control of the appearance of slow  $\alpha_2$ -globulin is incomplete in the 2 day post-partum maternal rat, because the globulin can be demonstrated in most adrenalectomized animals in this condition. (4) Adrenal cortical control over the appearance of slow  $\alpha_2$ -globulin is not simply absent in the post-partum maternal animal, because the percentage of adrenalectomized rats with demonstrable slow  $\alpha_2$ -globulin can be increased by the administration of corticosterone.

### Enzymes in Cultivated Human Fibroblasts derived from Patients with Down's Syndrome (Mongolism)

FORTY-SEVEN chromosomes have been found in cells of children with Down's syndrome<sup>1</sup>. The extra chromosome, a small acrocentric, is believed to be either number 21 or 22<sup>1-3</sup>. The finding of larger concentrations of alkaline phosphatase in leucocytes of patients with Down's syndrome<sup>4-6</sup> suggested that the gene determining the enzyme is located on the chromosome associated with mongolism. Increased concentrations of whole blood and leucocyte galactose-1-phosphate uridyl transferase<sup>7-12</sup>, erythrocyte and leucocyte glucose-6-phosphate dehydrogenase<sup>9-12</sup>, leucocyte acid phosphatase<sup>9,12</sup>, blood galactokinase<sup>10,13</sup>, erythrocyte phosphohexokinase<sup>14</sup> and leucocyte 5-nucleotidase<sup>12</sup> have been reported. On the other hand, no increase of glucose-6-phosphate dehydrogenase or acid phosphatase could be detected in the platelets of patients with Down's syndrome<sup>15</sup>.

Tissue culture techniques did not show any difference in concentrations of acid phosphatase and  $\beta$ -glucuronidase between strains derived from patients with Down's syndrome, 18 trisomy syndrome and D trisomy syndrome<sup>16</sup>. No difference between two strains of fibroblasts derived from Down's syndrome patients and eight strains from controls was found<sup>17</sup>.

In an attempt to determine whether the changes in peripheral blood of patients with Down's syndrome were

caused by the consistent influence of the genetic material carried by the extra chromosome, cultured cells derived from skin biopsies of trisomic Down's syndrome patients were examined.

Biopsies were obtained from ten trisomic mongoloid children and ten age-matched controls. After cleaning an area of the forearm, a sterile 26 gauge needle was inserted intradermally and skin was elevated. A piece of skin several millimetres long was removed from around the needle using sterile curved scissors. The biopsies were cut into several pieces, immobilized under cover slips in 35 mm Petri dishes containing culture medium (nutrient mixture F10, G.I.B. Co., 15 per cent foetal calf serum, 50  $\mu$ /ml. of penicillin and 50  $\mu$ /ml. of streptomycin), and placed in a carbon dioxide incubator. After 3-4 weeks the strains were sub-cultured and chromosome analyses were carried out by the method of DeMars<sup>18</sup>. After further sub-culture replicate aliquots of the appropriate cell suspensions were introduced into plastic Petri dishes and sampled at intervals during growth for determination of enzyme activity and protein content.

Glucose-6-phosphate dehydrogenase activity was measured by the procedure described by Zinkham and his co-workers<sup>19</sup>. The cells were mechanically disrupted in  $2 \times 10^{-5}$  molar nicotinamide-adenine dinucleotide phosphate. Assay was carried out in a system containing 60  $\mu$ moles of *tris*, 10  $\mu$ moles of magnesium chloride, 1.33  $\mu$ moles of NADP, and 6.6  $\mu$ moles of glucose-6-phosphate in a final volume of 1.0 ml. at 37° C. The blank contained all of the reagents except the substrate. Activity was expressed as changes in density at 340 m $\mu$ .

Activity of alkaline phosphatase was determined by the method of F. Walker (unpublished results). The cells were air dried and overlaid with 0.7 ml. of a mixture containing equal parts of 0.4 molar glycine, pH 9.2, and 0.001 molar *p*-nitrophenyl phosphate. Incubation was carried out at 37° C for 90 min, the reaction stopped by the addition of 0.3 ml. of Cox buffer and read at 410 m $\mu$ .

Activity of acid phosphatase was determined by the method of DeMars<sup>16</sup>. The cells were air dried and overlaid with 1.0 ml. of reaction mixture containing  $3 \times 10^{-4}$  molar *p*-nitrophenyl phosphate (PNP) in 0.4 molar sodium citrate buffer, pH 5.0. Incubation was carried out at 37° C for 60 min, 4.0 ml. of 0.1 normal sodium hydride was added, and the optical density was read at 410 m $\mu$ .

Galactose-1-phosphate uridyl transferase was assayed in fibroblasts using  $1-2 \times 10^6$  cells. The suspension of cells was sedimented, the supernatant fluid decanted, and the cells were homogenized with 50  $\mu$ l. of a 0.2 per cent solution of saponin. The enzyme activity was determined by incubating with UL-<sup>14</sup>C galactose-1-phosphate and measuring the formation of uridine diphosphate galactose-<sup>14</sup>C according to the procedure of Anderson *et al.*<sup>20</sup> as modified by Inouye and Hsia (unpublished results). Protein was determined by the method of Oyama and Eagle<sup>21</sup>. Data were either analysed daily or pooled, and no significant differences between strains derived from patients with trisomic Down's syndrome and controls could be demonstrated as shown in Table 1.

Several explanations have been offered to explain the changes in peripheral blood seen in Down's syndrome. It has been suggested that chromosome "21" might contain the "structural" genes for certain specific enzymes<sup>3,6,14</sup>, the "regulator" genes for certain groups of enzymes<sup>9,12</sup>, or the genes that regulate isoenzymes<sup>10</sup>. There is no convincing evidence for any of the above hypotheses.

Table 1. POOLED DATA FROM ALL EXPERIMENTS PERFORMED WITH FIBROBLASTS GROWN IN CULTURE FROM NORMAL CONTROLS AND PATIENTS WITH DOWN'S SYNDROME  
(All values are expressed as mean  $\pm$  standard error)

Enzyme	Controls	Down's

## MICROBIOLOGY

Enrichment of *Bacillus subtilis* Transformants by Zonal Centrifugation

A COMPETENT culture of *Bacillus subtilis* which has been exposed to DNA consists of at least two metabolically distinct cell populations—competent cells which have taken up DNA and are potentially transformable, and untransformable cells. The potential transformants are relatively resistant to penicillin, actinomycin D, and puromycin and appear to be non-dividing (refs. 1–3 and personal communication from H. O. Kammen, R. H. Beloff, and E. S. Canellakis). We suspected that these cells were lighter than the majority of actively dividing incompetent cells. Zonal centrifugation of a competent culture of *B. subtilis* in a sucrose gradient shows that these two kinds of cells can, in fact, be separated.

The media and transformation procedures were those of Anagnostopoulos and Spizizen<sup>4</sup>. *B. subtilis* strain 168 *ind*<sup>-</sup> (indole requiring) was used as the recipient and *B. subtilis* 168 prototroph as the donor of DNA. The DNA was extracted by the method of Marmur<sup>5</sup>. About 10 ml. of a linear sucrose gradient (4.5 per cent w/v to 18 per cent w/v sucrose in 0.1 molar sodium chloride and 0.05 molar sodium citrate at pH 7.4) was layered in a sterile 5/8 in. × 3 in. cellulose nitrate centrifuge tube by means of a gradient apparatus. The solutions were sterilized by filtration.

A competent culture of *B. subtilis ind*<sup>-</sup> was exposed to 5 µg/ml. of prototrophic DNA for 40–50 min at 37° C (ref. 4). The cells were centrifuged and resuspended in one tenth of the original volume of the medium and 0.2 ml. of this suspension was layered on the top of the sucrose gradient. The tubes were centrifuged for 30–40 min at 1,000–2,000 r.p.m. in the swing-out head of an 'MSE minor' clinical centrifuge at room temperature (~22° C). The cells move as a visible band, the position of which at any time can be determined by inspection. The tubes were connected to a drop collecting device<sup>6,7</sup> and punctured. Five drop fractions were collected serially. Alternate fractions were assayed for transformation to prototrophy and the viable count. The sucrose concentration along the gradient was measured by an 'Abbe-3L' refractometer.

The results of a typical experiment are given in Fig. 1. The majority of the transformed cells form a peak (A), which is quite distinct from the peak (B) formed by the

An alternative suggestion is that enzyme activity in the leucocyte and possibly also in the erythrocyte is dependent on cell age and that the shortened life span of the leucocyte in Down's syndrome results in the presence of younger white cells with higher enzyme concentrations<sup>22,24</sup>. Measurement of the survival of granulocytes in four adult patients with Down's syndrome, however, has demonstrated no significant difference from normal<sup>25</sup>.

Significant differences have been reported between trisomic and translocation Down's syndrome patients for the following enzymes: leucocyte, erythrocyte, and whole-blood galactose-1-phosphate uridyl transferase, leucocyte acid phosphatase, leucocyte alkaline phosphatase, erythrocyte glucose-6-phosphate dehydrogenase, and leucocyte 5-nucleotidase<sup>12</sup>. The translocated position of the chromosome could perhaps interfere with the normal gene action (position effect) or the deletion occurring in the process of translocation could be the site on the chromosome which determines the expression of the enzymes<sup>12</sup>.

The different responses of these enzymes between fibroblast cultures and leucocytes of trisomic Down's syndrome patients suggest that the increased activity of certain enzymes reported in trisomic individuals cannot be interpreted in terms of either gene locations or triple gene dose effect. The difference may be caused by one or more of the following: (a) specific properties of the white blood cell, including shortened life span; (b) tissue specific variation in enzyme regulation; (c) isoenzymes with different control mechanisms; (d) more complicated genetic interactions, and (e) effect of tissue culture.

We thank Dr. Paul Tillman of the Dixon State School for his co-operation and Carol Neapolitan, Joan Gordon, and Bonnie Williams for technical assistance. This work was aided by grants from the Illinois Mental Health Fund and the U.S. Public Health Service.

Fig. 1. Sedimentation of a competent culture of *B. subtilis* 168 *ind*<sup>-</sup> in a sucrose gradient. The percentage of transformation in the unfractionated culture was 0.015. O, Percentage of transformation; ●, cell titre; Δ, percentage of sucrose.

bulk of the cells. The frequency of transformants in the peak fraction is four to eight times greater than the average transformation frequency of the culture. By collecting smaller fractions enrichment greater than this can be easily obtained.

The centrifugal fractionation of a competent culture in addition to yielding higher transformation frequencies provides a convenient method for investigating the metabolic properties of the potential transformants.

### Brief Consideration of the Meaning of the Lysogenic Conversion in *Salmonella anatum* Phage System

THE unusual properties of the  $\epsilon$ -group of *Salmonella anatum* phages to change the antigenic structure of the surface of their host bacterium first described by Uetake<sup>1,2</sup> are also interesting from the point of view of their biological meaning. The results given by Uetake seem to justify this approach. Uetake found that a non-lysogenic strain of *Salmonella anatum* (A) with antigenic structure 3,10 and sensitive to the phage  $\epsilon$ -15, when lysogenized by it, gives rise to a lysogenic strain A ( $\epsilon$ -15) with antigenic structure changed from 3,10 to 3,15 and sensitive to the phage  $\epsilon$ -34. When this new strain (with antigenic structure 3,15) is lysogenized by  $\epsilon$ -34, the resulting strain, containing both prophages A ( $\epsilon$ -15,  $\epsilon$ -34), has again a new antigenic structure (3) (15) 34. When the original strain A (with antigenic structure 3,10) is lysogenized in special conditions by  $\epsilon$ -34 only<sup>3</sup>, no antigenic change occurs. On the basis of a very detailed analysis the authors conclude that the information for the antigenic change was brought into the cell by the infecting phage and that for the formation of the antigen 34 a mechanism for the synthesis of antigen 15 is required, so that a "genetic co-operation" between the two phages occurs.

The results of these experiments as given by Uetake<sup>2</sup> are:

Strain	Plaque formation		Killing		Adsorption	
	$\epsilon$ -15	$\epsilon$ -34	$\epsilon$ -15	$\epsilon$ -34	$\epsilon$ -15	$\epsilon$ -34
	virulent	virulent	virulent	virulent	virulent	virulent
A	+	-	+	-	+	-
A( $\epsilon$ -15)	-	+	-	+	-	+
A( $\epsilon$ -34)	+	-	+	-	+	-
A( $\epsilon$ -15, $\epsilon$ -34)	-	-	-	-	-	-

Without regard to the chemical basis of this phenomenon<sup>4</sup> we find an interesting correlation; the bacteria lysogenic for  $\epsilon$ -15 do not adsorb  $\epsilon$ -15, the strain lysogenic for  $\epsilon$ -34 does not adsorb the phage  $\epsilon$ -34, and the strain lysogenic for both phages does not adsorb either of them. Thus, the changes caused by the lysogenization seem to serve as a tool depriving the bacterial host of the affinity to the phages related to the prophages present. Apparently, the phages carry information for the changes of their own receptors on the host cell. On the other hand, the  $\epsilon$ -34 phage introduced "by mistake"<sup>2</sup> to the strain A non-lysogenic for  $\epsilon$ -15 does not cause any detectable changes of the host's surface properties.

This view throws a new light on the meaning of the lysogenic conversion in this system. The logic of this

phenomenon, that is the tendency to prevent superinfection by the homologous phage, may be closely related to that of lysogenic immunity. This new barrier seems to be far more efficient, because it prevents superinfection by the relatively frequent virulent mutations which overcome the cytoplasmic immunity of the lysogenic cell. A host mutation, on the other hand, would have to be a virulent one to infect this lysogenic cell, a double mutant, which is unlikely to occur.

In view of this, it may be unnecessary to differentiate between strictly viral genes and those responsible for lysogenic conversion. The problem of the origin of the latter—so often discussed (see, for example, ref. 1, p. 504; and ref. 3, p. 209)—could merge with that of the phylogenetic origin of the phage itself. The existence of lysogenic conversion would seem to support the idea of Campbell<sup>5</sup> that phage genes advantageous to the host would be preferred and selected during evolution because they compensate for the handicap the phage imposes on the host and thus enable the host bacteria—and therefore its phage—to survive.

### Linkage of Arginine-sensitive (*ars*) and Uracil-Arginine Requiring (*pyrA*) Loci of *Salmonella typhimurium*

ISHIDSU<sup>1</sup> has isolated a mutant (*ars-I*) of *Salmonella typhimurium* that grows normally on a minimal medium but is strongly inhibited on addition of arginine. This sensitivity to arginine can be overcome by the addition of uracil.

With the knowledge that genes controlling co-ordinated functions are often clustered together<sup>2</sup>, co-transduction experiments were performed to determine whether the *ars-I* locus is closely linked to a locus for a related biochemical step, such as biosynthesis of arginine and (or) uracil. As can be seen in Table 1, it was found that *ars-I* is closely linked to *pyrA*, single step mutants of which require both uracil and arginine<sup>3</sup> (see Sanderson and Demerec<sup>4</sup> for linkage map of *S. typhimurium*).

The procedure for joint testing for joint transduction was to grow donor phage P22 on *ars-I*. For each transductant plate, about  $2 \times 10^8$  phage particles were added to 0.1 ml. of an overnight culture of each of the *pyrA* recipients (about  $2 \times 10^8$  cells/ml.) and the mixture was spread on the surface of the plate containing minimal agar. After 2 days of incubation, transductant colonies formed; these represented transfer of donor *pyrA*<sup>+</sup> to *pyrA* recipient cells. The next step was to determine how many of the transductants also received the *ars-I* mutational site along with the *pyrA*<sup>+</sup>. This was scored in two different ways: (1) transductant colonies were replica plated on to plates containing minimal agar plus 100  $\mu$ g of arginine/ml. A large fraction (Table 1) of the transductant colonies

Table 1. JOINT TRANSDUCTION OF ARGININE-SENSITIVE (*ars-I*) AND URACIL-ARGININE (*pyrA*<sup>+</sup>) SITES IN *S. typhimurium*

Test No.	Recipient	No. of <i>pyrA</i> <sup>+</sup> transductants	No. containing <i>ars-I</i>	Percentage co-transduction
1	<i>pyrA</i> 47	53	31	58
2	<i>pyrA</i> 127	58	32	55
3	<i>pyrA</i> 129	106	32	30
4	<i>pyrA</i> 180	146	87	60
5	<i>pyrA</i> 180	92	41	45
6	<i>pyrA</i> 180	106	44	41
7	<i>pyrA</i> 180*	121*	0*	0*

\* Control, in which wild type *ars-I*<sup>+</sup> donor phage was substituted for *ars-I*

failed to grow, and on testing were found to contain the *ars* mutation; (2) it was found in later experiments that *pyrA*<sup>+</sup> *ars-1* colonies could be distinguished from *pyrA*<sup>+</sup> colonies without the need for replica plating. By incorporation of a small amount of arginine (2 µg/ml.) in the initial transductant plates, those recipient cells that had received the *ars-1* mutation as well as the *pyrA*<sup>+</sup> were smaller in size as a result of the arginine sensitivity. Testing of individual transductants showed that scoring by colony size was completely accurate.

In *S. typhimurium*, *pyrA* probably controls the biosynthesis of the enzyme glutamino-carbamoyl phosphate synthetase, as in *E. coli*<sup>5</sup>. It is interesting to note that a uracil-sensitive (*urs*) locus in *E. coli* is also linked to *pyrA* (ref. 6).

The arginine sensitivity of *ars-1* and its relationship to the enzymes involved in arginine-uracil biosynthesis is now being investigated by Ishidsu<sup>1</sup>.

This research was carried out at Brookhaven National Laboratory under the auspices of the U.S. Atomic Energy Commission, and was supported by a U.S. National Science Foundation grant.

### Rapid Method for the Quantitative Estimation of Microbial Lipases

THE investigation of microbial lipases has been considerably impeded by a lack of knowledge about their natural substrates and their physiological role in the metabolism of the organisms. Any substrate chosen to detect microbial lipases must therefore be arbitrary and it is difficult to evaluate data of different workers because of the wide choice of substrates, assay conditions and methods employed. The underlying principle in the assay of microbial lipases has usually been the estimation of free fatty acids liberated from triglycerides after a suitable incubation time. We have found that direct titration methods are not suitable, because most cultures contain alkaline or acid degradation products. This can be overcome by extracting the fatty acids from the medium after incubation with the substrate<sup>1</sup> but the procedure is laborious and difficult to carry out quantitatively. A long incubation time is also open to the criticisms that the products of lipolysis may inhibit lipase activity<sup>2-4</sup> or be used in the reverse, synthetic reaction<sup>5</sup>. Short duration assays have been developed such as the indirect manometric method employed by Forster and co-workers<sup>6</sup> or the direct method of continuous automatic titration of the acid liberated from an appropriate substrate in a pH stat<sup>7</sup>, but the lipase activities of the micro-organisms that we have tested have been too low to be assayed by such techniques.

The fact however, that all of these micro-organisms produced zones of hydrolysis when grown on tributyrin agar, and some when grown on butterfat-Victoria blue agar media<sup>8</sup>, suggested that it should be possible to develop an agar diffusion method that would be more sensitive and versatile than existing assay techniques. Proteins diffuse through agar gel as through a plain solvent when the concentration of agar is below 1.5 per cent<sup>9,10</sup>. Cooper<sup>11</sup> has shown that the mathematical conditions for a valid

agar diffusion assay are that the relationship between the logarithm of the enzyme concentration and the zone radius (or its square) must be linear and that the ratio of response for high and low dilutions of the standard must be the same as for the unknown. Carter and Sykes<sup>12</sup> assayed several enzymes by an agar diffusion method, but they failed to find a suitable substrate for the assay of pancreatic lipase. Preliminary experiments in this laboratory indicated that emulsified triglycerides, particularly tributyrin, were suitable substrates and the following thin layer method was developed.

Ten ml. of a 1 per cent emulsion of tributyrin, or equivalent molecular concentrations of other synthetic triglycerides in water (prepared by passing the mixture four times through an Ormerod QP homogenizer at a pressure of 1,000 lb./sq. in.), are added to 90 ml. of a hot solution of Davis agar (1.2 per cent) in M/20 phosphate buffer (usually pH 8). One ml. of this emulsion is spread over an area, 2 in. by 1 in. of a microscope slide, a hole 2.3 mm in diameter is bored with a thin steel tube and 0.004 ml. of the lipase solution added by means of an Agla micro-syringe. The slide is placed in a Petri dish containing moist absorbent cotton wool and incubated at 30° for periods up to 48 h. The diameters of the zones of clearing are measured with Vernier callipers.

Since many workers<sup>13-15</sup> hold the view that the hydrolysis of tributyrin is not an indication that more complex natural triglycerides such as butterfat will be attacked, we have also developed a thin layer agar diffusion method for the detection of lipolytic activity against butterfat. The lipase is added to a phosphate buffered agar gel, on which is then placed a lens tissue (Green, 105), which has been painted with melted butterfat saturated with Victoria blue. The hydrolysis of the thin uniform layer of butterfat is shown as a blue zone against the red background of unchanged dye.

The quantitative validity of these agar diffusion assays was determined with a micrococcus (*M. freudenreichii*, NCDO 1223). The organism was grown in 1 per cent Bacto peptone pH 7.0 and the extracellular lipase concentrated by a factor of 100 by precipitation with ammonium sulphate. The rate of hydrolysis, as measured by the clearing of tributyrin and trioctanoin emulsions, was proportional to the period of incubation (Fig. 1) and remained linear for at least 48 h. Maintaining the lipase preparation at 80° for

Fig. 1. Hydrolysis of 0.1 per cent (v/v) tributyrin (O) and trioctanoin (●) by a partially purified lipase of *Micrococcus freudenreichii* over an extended period of incubation.  $x$  is the diameter of the zone of clearing of the emulsion minus the diameter of the well.

Fig. 2. The rate of hydrolysis of equimolecular concentrations of various triglycerides by dilutions of a partially purified lipase from *Micrococcus freudenreichii* after 19 h at 30°. O—O Tributyrin (0.1 per cent, v/v), ●—● triolein (0.17 per cent, v/v), Δ—Δ tridecanoin (0.2 per cent, v/v), ▲—▲ butterfat-Victoria blue. x is the diameter of the zone of clearing of the emulsion minus the diameter of the well.

2 min completely destroyed its activity, showing that non-enzyme hydrolysis was not responsible. A linear relationship was also obtained when the logarithms of dilutions of the concentrated lipase were plotted against the diameter of the zone of hydrolysis obtained with various emulsions (Fig. 2) after a certain period of incubation at 30° C. The slopes of these straight lines were parallel, indicating that a single enzyme system was responsible for the hydrolysis of all four substrates. The points where these lines cut the axis are the minimal lipase concentrations which give discernible zones with a particular substrate. These could be calculated and confirmed by experiment. A dilution of 1 in 17,500 of the purified lipase was the smallest concentration that gave a zone with tributyrin emulsion, 1 in 2,500 with triolein or tridecanoin emulsion and 1 in 200 for the butterfat-Victoria blue medium. The tributyrin emulsion assay was therefore almost 90 times more sensitive than the butterfat assay. Similar results were obtained with a pseudomonas (*P. fragi*, NCDO 752).

The supernatants from growing cultures of both the organisms used in this investigation readily cleared tributyrin agar emulsions but showed no activity against butterfat. When the lipase in the supernatant was concentrated by ammonium sulphate precipitation, however, the butterfat was readily hydrolysed. The sensitivity of the tributyrin emulsion assay lies not only in the use of a thin layer of agar containing a very low concentration of tributyrin<sup>16</sup> which produces easily distinguished transparent zones. If the concentration of tributyrin is increased the zone of clearing obtained in a given time with a lipase preparation is decreased and a 1 per cent tributyrin emulsion gives zones that are approximately equivalent to those obtained with the butterfat-Victoria blue medium. We consider that the sensitivity of the tributyrin emulsion assay makes it particularly suitable for the screening of micro-organisms for lipolytic activity and that the use of butterfat agar means that many weakly lipolytic organisms are overlooked. Over extended periods this low activity against natural fats, as in the storage of butter or in cheese ripening, could be of great significance.

The thin layer diffusion assay was developed specifically for microbial lipases to overcome the disadvantages of methods which are affected by buffers and the degradation products normally found in microbial cultures. In addition it has been used successfully to determine the activities of lipases from skim milk, pig pancreas and rat adipose tissue, since the ease with which the assay can be

carried out and the small size of the sample needed make it particularly useful for following the purification of lipases by column procedures. The relative lipolytic activities in the fractions off 'Sephadex' columns were identical whether determined as the liberation of free fatty acids in a pH stat (in mμequiv./min) or by the rates of clearing of a tributyrin emulsion.

## RADIOBIOLOGY

### Peroxidase Isozymes in Barley Leaves from Irradiated Seeds

It is known that ionizing radiations cause an increase in peroxidase activity<sup>1-3</sup>, but it has not yet been explained how they do this. Although multiple forms of peroxidase have been shown in plants<sup>4-6</sup>, no effect of radiations on these forms has yet been described. This communication reports the appearance, in the zymograms of barley leaves which develop from irradiated seeds, of new peroxidase bands with respect to the control.

Plants of barley cv. Esau from irradiated (60 kR. of X-rays) and unirradiated seeds were grown in sand in the greenhouse at 22° C with a 15 h photoperiod. First leaves of 8 day old seedlings were cut and homogenized by grinding in a mortar with 0.066 molar phosphate buffer at 4° C. The homogenate was centrifuged at 20,000g for 20 min and the precipitate was discarded. The supernatant was saturated with ammonium sulphate and the precipitate was removed, 3 h later, by centrifugation at 20,000g for 20 min. The precipitate was dissolved in 2.4 ml. of buffer composed of nine parts of 0.016 molar tris-0.033 molar citric acid (pH 8.1) and one part of 0.02 molar lithium hydroxide-0.076 molar boric acid (pH 8.1)<sup>7</sup> and then dialysed for 20 h against three successive volumes of 200 ml. of the same buffer in a cold room. The final residue in the dialysis bag was again clarified by centrifugation. Starch-gel electrophoresis was carried out as described by Klapper<sup>7</sup> for 3 h at 4° C with a constant current of 25 m.amp (450-400 V) passing through the gel bed (14 × 10 × 0.6 cm). After completion of the run, the gels were flooded for 1 min in benzidine-saturated water containing 0.3 per cent hydrogen peroxide and then in methanol, acetic acid and water (50:10:40). The regions of gel containing peroxidase turned blue immediately and afterwards turned brown. The zymogram of peroxidase from irradiated barley shows five peroxidase isozymes at the cathode and four at the anode, while the zymogram from unirradiated barley shows only three isozymes at

Fig. 1. Electrophoretic pattern of peroxidase isozymes in leaves from irradiated and unirradiated barley seeds.

the cathode and two at the anode (Fig. 1). In the zymogram of the leaves from irradiated seeds, therefore, there is the appearance of two new bands at the cathode (46 mm and 33 mm from the origin) and of two bands at the anode (11 mm and 25 mm from the origin). The staining intensity of all the bands in irradiated material is higher than in the controls, showing a greater enzyme activity. It may be concluded that the irradiation of seeds causes deep alteration of the system which regulate the biosynthetic pattern. This alteration causes a differentiation of forms of the peroxidase isozymes, the biological significance of which remains to be established.

### Protection by Substrate Analogues from Ultra-violet Damage of Bovine Pancreatic Ribonuclease

THERE is a great deal of evidence that the sensitivity to ionizing radiation of an enzyme is influenced by the presence of a substrate or a substrate analogue in the medium. For example, bovine pancreatic ribonuclease (RNase) is protected by a substrate analogue from damage by  $\gamma$ -irradiation and a modified active enzyme is formed<sup>1</sup>. Little work has been done, however, on the effect of a substrate or a substrate analogue on damage to an enzyme by ultra-violet light. We found that several substrate analogues protected RNase from damage by ultra-violet light.

RNase A solution was obtained by 'Amberlite IRC-50' chromatography<sup>2</sup> from a commercial preparation and dialysis against an acetate buffer (pH 5.6 and ionic strength 0.01) containing  $10^{-4}$  molar ethylenediamine tetraacetic acid (EDTA). The mixture of the enzyme ( $1 \times 10^{-5}$  molar) and a substrate analogue ( $2 \times 10^{-5}$  molar) in the buffer was placed in a quartz cell of optical path 2 mm and irradiated with a low pressure mercury germicidal lamp from a distance of 8 cm at  $2^{\circ}$ – $4^{\circ}$  C. (The pH of 5.6, low ionic strength and low temperature are favourable for making a complex of enzyme and a substrate analogue<sup>3</sup>.) Intensity of the irradiation energy (2537 Å) was measured with an ultra-violet dosimeter calibrated with a chemical actinometer<sup>4</sup>. Immediately after the irradiation, the remaining enzyme activity was measured without any pretreatment to eliminate the substrate analogue from the irradiated mixture. The enzyme activity was measured by an increase in an acid-soluble fraction by the enzyme ( $10^{-7}$  molar) over the substrate (at pH 7.3) which was yeast RNA (0.3 per cent).

The inactivation curves of RNase were log-linear, as shown in Fig. 1, both in the absence and presence of a substrate analogue, and some substrate analogues showed a protective effect. The degree of protection was expressed as follows. A slight correction for shielding of ultra-violet light by a base component of substrate analogue was made. It was estimated as 4 per cent for uridine and cytidine, 6 per cent for guanosine, and 7 per cent for adenosine. The degree of protection was defined as  $(1 - a/b) \times 100$  per cent, where  $a$  and  $b$  are the corrected gradients of the slope in the absence and presence of the substrate analogue, respectively.

As summarized in Table 1, substances which cannot make a complex with the enzyme (which implies all nucleosides) are ineffective for protection, and nucleotides "transparent" with respect to absorption of ultra-violet, namely ribonucleotides of dihydrouracil and uracil hydrate, also have no effect. In general, a 3'-ribonucleotide is more effective than the other isomers, and all nucleotides of cytosine tested have a remarkable protective effect.

The protection by cytidine-2'(+3')-phosphate was not influenced by oxygen in the medium.

Mechanism of the protection by a substrate analogue is not yet clear. Complex formation of the enzyme with the substrate analogue and absorption of ultra-violet energy by the latter are supposed to be involved in the process of the protection.

Fig. 1. Inactivation curves of RNase by ultra-violet light with and without substrate analogues. Dose rate is  $4,940 \text{ erg/mm}^2 \text{ min}$ .

### Protective Effect of Cystamine and AET given at Various Intervals before Irradiation

Using the spleen colony technique described by Till and McCulloch<sup>1</sup>, we investigated the dose reduction factor for cystamine on haematopoietic stem cells by examining the endogenous colonies in the spleen of control and protected mice. We found that the size of the dose reduction factor varies noticeably with the time which has elapsed between the intraperitoneal injection of cystamine and the irradiation, particularly during the first 15 min after the administration of this radioprotective substance<sup>2</sup>. In the experiments reported here mice were irradiated at a greater dose rate (436 r./min). We were thus able to

Fig. 1. The relation between the exposure and mean number of colonies/spleen of mice in the first experiment. C, Control group; E<sub>1</sub>, E<sub>2</sub> and E<sub>3</sub>, groups of experimental mice. Vertical bars illustrate the standard deviation of the mean.

Fig. 2. The relation between the exposure and mean number of colonies/spleen of mice in the second experiment. C, Control group; E<sub>1</sub>, E<sub>2</sub> and E<sub>3</sub>, groups of experimental mice. Vertical bars illustrate the standard deviation of the mean.

shorten the irradiation time and demonstrate that cystamine showed its maximum radioprotective effect from the fourth to the sixth minute after it had been intraperitoneally injected. Similar results were obtained with 2- $\beta$ -amino ethyl isothiuronium (AET). The results will be quoted briefly in this article; they will be published in detail elsewhere.

Mice C57BL were given whole-body X-ray (200 kV, 20 m.amp, half value layer 1.02 mm copper, focus-distance 20 cm, exposure rate 436 r./min) exposures. The animals were divided into four groups; the control mice were only irradiated; the mice in experimental groups were injected intraperitoneally with cystamine (di-2-aminoethylsulphide . 2 HCl; 160 mg/kg) or AET (2-aminoethylisothiuronium . Br . HBr; 200 mg/kg). There were some sub-groups in each group of mice, distinguished from each other by radiation exposure only; ten to sixteen mice were put in each sub-group. All mice were killed nine days after the beginning of the experiment; their spleens were removed and fixed. Macroscopically visible colonies were counted and the standard deviations of the mean numbers of colonies for each spleen were calculated. From these data, the regression lines were constructed for each group.

In the first experiment, the mice protected with cystamine were divided into three groups according to the interval between the injection and the middle of the irradiation time. The duration of these intervals was: in the first experimental group (E<sub>1</sub>) 3 min, in the second (E<sub>2</sub>) 5 min and in the third (E<sub>3</sub>) 8 min. The results are shown in Fig. 1. The dose reduction factors for each experimental group were calculated from the ratio of the effective exposures for four colonies on the regression lines compared with the control group. We found that the radioprotective effectiveness of cystamine was greatest in the E<sub>2</sub> group (dose reduction factor Q2.32), that is, when the injection of cystamine was given 5 min before the middle of the irradiation time. If this interval was shorter (3 min by the E<sub>1</sub> group) or longer (8 min by the E<sub>3</sub> group), the level of the protection was smaller (dose reduction frequency by the E<sub>1</sub> group, 1.61; and by the E<sub>3</sub> group, 1.82).

The arrangement of the second experiment was similar to the first one, but experimental mice were given AET instead of cystamine. The group of control mice included two sub-groups only and the intervals from the injection of AET till the middle of the irradiation time were 4 min in the E<sub>1</sub> group, 6 min in the E<sub>2</sub> group and 9 min in the E<sub>3</sub> group. The results are demonstrated in Fig. 2. In order to make survey easy, only the regression lines for control

and  $E_2$  groups were drawn. Dose reduction factors were calculated in the same manner as for the first experiment. They were: 1.86 for the  $E_1$ , 1.95 for the  $E_2$  and 1.90 for the  $E_3$  group. Thus, the radioprotective effectiveness of AET did not differ in any striking way at all intervals used in the second experiment.

Our results give evidence which favours an assumption that the radioprotective efficacy of cystamine and AET on haematopoietic stem cells in the spleen of irradiated mice is brought about soon after these substances have been intraperitoneally injected. Dose reduction factors for both substances are greatest when administered between 4 and 7 min before irradiation. The dose reduction factor for cystamine is higher than that for AET. After longer intervals the radioprotective effect of cystamine decreases quickly, even as early as at 8 min after the injection the dose reduction factor being no higher than that of AET. We realize that the change of the radioprotective effectiveness of cystamine on haematopoietic spleen stem cells takes place so quickly that we are not able to assess it accurately. Nevertheless, we conclude that the radioprotective effect of cystamine on the haematopoietic stem cells in the spleen of irradiated mice shows a remarkably short peak in relation with AET. This maximum of efficacy may be explained by the difference in the metabolism of these two substances and by the pharmacological properties of cystamine.

We thank Mrs. M. Fabová and Mrs. J. Čecháčeková for technical assistance.

### Transient Changes in the Radiosensitivity of Mammalian Cells on Transfer from *in vivo* to *in vitro* Culture Conditions

CONDITIONS of culture are well known to play an important part in determining the radiation response of micro-organisms. Mammalian cells grown *in vitro* only remain viable within a rather limited range of culture conditions and, perhaps for this reason, only a few reports are available of the radiobiological consequences of changing their culture conditions<sup>1-3</sup>.

The effects of one type of change have been investigated using cells of the Ehrlich diploid mouse ascites tumour which have been grown *in vitro* for 3 yr. It was found that the radiobiological response was profoundly affected if cells which had previously been grown *in vitro* were allowed to grow *in vivo* for some generations and were then transferred to *in vitro* conditions before irradiation. The effect was transient and disappeared within the period of the first *in vitro* cell division.

Cells have been grown routinely *in vitro* as a monolayer on the surface of glass bottles; for survival curve experiments, cells were prepared from these cultures in one or other of two ways. The monolayer was first dispersed with trypsin, then the cells were either plated directly on to Petri dishes or they were inoculated into the peritoneal cavity of a mouse. In this case an ascites tumour, which was a single cell suspension needing no further trypsin treatment, developed in about three weeks. These cells retained their ability to develop into clones when they were plated on to Petri dishes. Cells which were plated immediately after trypsinization of a monolayer culture

will be referred to as "bottle cultured" or *B.C.* cells and cells which were grown in a mouse will be referred to as "mouse cultured" or *M.C.* cells.

Both *B.C.* and *M.C.* cells became attached to the surface of 'Nunc' plastic Petri dishes within 1 h of being plated. The usual plating efficiencies were about 65 per cent and 50 per cent for *B.C.* and *M.C.* cells, respectively. Cells were irradiated, after removal of the growth medium, with 250 kVp X-rays at a dose rate of 253 rads/min.

The radiation sensitivity of the two types of cell was markedly different (Fig. 1). Twice the dose was required to reduce *B.C.* cells to the same level of survival as *M.C.* cells in the presence of oxygen; this result was not affected when *M.C.* cells were treated with trypsin before they were plated. The difference was even more pronounced when the cells were anoxic during irradiation; the ratio of doses producing the same level of survival was 2.5. The additional enhancement in the sensitivity of *M.C.* cells irradiated anoxically was reflected in the oxygen enhancement ratios for the two types of cell, which were 2.7 for *B.C.* cells and 2.0 for *M.C.* cells.

The difference in sensitivity between *B.C.* and *M.C.* cells almost disappeared after the *M.C.* cells had been in *in vitro* conditions for a period before irradiation. In these experiments *M.C.* cells were removed from a mouse and put into culture bottles containing growth medium. These were incubated at 37° C for the selected length of time, after which the cells, by then attached to the glass, were removed with trypsin, plated on to Petri dishes in the usual way and irradiated. The sensitivity of the *M.C.* cells decreased with time spent *in vitro* before irradiation and approached that of the *B.C.* cells (Fig. 2). A dose of 364 rads given in air to cells 1 h after plating killed fifteen times as many *M.C.* as *B.C.* cells. This factor was reduced to 1.5 when *M.C.* cells had been incubated *in vitro* for one day before the irradiation was given. Observations were made on the change in sensitivity over the first 18 h after transferring *M.C.* cells to *in vitro* culture conditions. The sensitivity did not begin to decrease for about 8 h; there may have been a slight increase during this time (Fig. 3).

From these experiments it can be seen that the transition from *in vivo* to *in vitro* culture conditions caused an immediate increase in sensitivity of the cells from which

Fig. 1. Survival curves of *B.C.* and *M.C.* cells.  $\Delta$ , *M.C.* cells, oxic;  $\square$ , *M.C.* cells, anoxic;  $\times$ , *B.C.* cells, oxic;  $\circ$ , *B.C.* cells, anoxic.

they slowly recovered. To examine the effect of keeping the cells *in vivo* after irradiation but before plating, a mouse bearing a tumour of *M.C.* cells was irradiated. Immediately after the irradiation and at times up to 4 h later, cells were withdrawn from the mouse, counted, diluted and plated. Because there is evidence to show that a large proportion of cells in a well developed ascites tumour is anoxic<sup>4,5</sup>, the mouse was given pure nitrogen to breathe before and during the irradiation to ensure that the whole population was anoxic. As mice can breathe nitrogen for only about 45 sec before they die, a high

Fig. 2. Change in sensitivity of *M.C.* cells after a period of *in vitro* culture.  $\circ$ , 728 rads, anoxic;  $\Delta$ , 364 rads, oxalic;  $\square$ , 1,246 rads, anoxic;  $\times$ , 622 rads, oxalic. Arrow points to survival of *B.C.* cells to the same dose.

Fig. 3. Change in sensitivity of *M.C.* cells to a dose of 364 rads given in air, after a period of *in vitro* culture. Symbols represent two separate experiments. Arrow points to survival of *B.C.* cells to the same dose.

Fig. 4. Change in colony-forming ability of *M.C.* cells with the time they were left in the mouse after irradiation. All samples received 1,200 rads of electrons anoxically. *a*, Survival level of *B.C.* cells and, *b*, survival level of *M.C.* cells, irradiated on Petri dishes 1.75 h after plating.

dose rate was required for the irradiation. This was achieved by using the beam of 8 MeV electrons from the Medical Research Council linear accelerator. The longer the cells were left in the mouse after a given dose the greater was the number of cells able to give rise to colonies when they had been plated (Fig. 4). The increase in surviving fraction when the cells were left in the mouse for 4 h after irradiation was too large to be accounted for by division of surviving cells within the mouse. It may be that the operative mechanism was similar to that which resulted in the increase of survivors observed when *M.C.* cells were kept *in vitro* before irradiation.

Supporting evidence for the transience of the change in sensitivity observed with change in growth conditions of these cells comes from experiments reported by Cullen and Hornsey<sup>6</sup>. Survival curves constructed from results obtained using cells cultured *in vitro* throughout were very similar to those which had been obtained by Silini and Hornsey<sup>7</sup> from experiments in which cells had been grown *in vivo* and subsequently assayed *in vivo*.

The phenomenon in which culture conditions exert a markedly differential action on the sensitivities of cells irradiated in oxia and anoxic conditions has frequently been demonstrated with micro-organisms<sup>8-10</sup>. The only previous demonstration of the effect on mammalian cells seems to have been that by Berry<sup>11</sup>, who found that HeLa cells grown in the presence of "methotrexate" were more radiosensitive than cells grown in normal culture medium and that they also had a reduced oxygen enhancement ratio. Berry<sup>11</sup> suggested that his results might have been caused, in part, by a synchronization of the cell population, but no evidence of synchronization of *M.C.* cells has been found in these experiments.

If cells were normally capable of repairing some of the damage caused by irradiation, these results could be accounted for by the mechanism of repair becoming much less effective for a period after transfer from *in vivo* to *in vitro* culture conditions and gradually becoming more effective again within about 24 h.

Whatever the nature of this repair process, it is more effective when the cells have been irradiated in anoxic conditions so that it must be acting on a component of damage which plays a greater part in these conditions.

This suggests that such damage is associated with an oxygen enhancement ratio which is intrinsically lower than the overall ratio<sup>12</sup>.

## PSYCHOLOGY

### Ultra-kinaesthetic Judgment of Size

AN investigation has been carried out on some numerical links between visual space and a kinaesthetic sensitivity to spatial relationships. One type of experiment (purely visual) is based on Luneburg's concept of non-Euclidean visual space<sup>1</sup> and on its modification by Blank<sup>2</sup>. I have designed another type of experiment (visuo-kinaesthetic)<sup>3</sup> to investigate some effects of proprioception on vision. In these experiments an observer imagines himself moving towards two distant light points in the darkness and passing his forearm between them. He adjusts the gap between the two light points by remote control so that it equals the length of his forearm. The variables are  $C$ , the size of the gap between two light sources in a frontal plane, and  $R$ , the size of the forearm of the observer. (Other dimensions of the observer's body are considered in other trials.) These variables are compared with  $K$ , Luneburg's curvature of visual space, and  $r$ , the subjective distance of the stimuli from the eyes, as given by Blank in units of  $(-K)^{-\frac{1}{2}}$ . The experiments show that  $C$  (which is approximately equal to  $R$  close to the observer) contracts sharply in the case of negative curvature with an increasing distance from the eyes (to a value several times smaller at a distance of several yards) but remains approximately constant with  $K \sim 0$  and expands with  $K > 0$ .

For a selected experimental condition,  $C$  and  $R$  predict  $K$  and  $r$  (and vice versa) with considerable numerical accuracy. For a wider range of experimental distances and for extreme values of  $K$  and  $r$  some of the numerical accuracy is lost. (This is related to the known difficulties in determining  $K$  and  $r$  for wide ranges.) Statistical differences between the observers, however, remain highly significant. Using a more general approximation to the curves of  $C$  against  $r$ ,

$$C \sim R(\cosh r)^{-1}$$

the meaning of  $C$  as a proportion of  $R$  can be outlined. A small  $C$  (with large  $\cosh r$  and high negative curvature) indicates that an observer uses a small unit in assessing size (allowing for visual angle which diminishes with distance) so that he assesses the size as relatively large. But when for a relatively great physical distance  $C$  approximates  $R$  (with  $\cosh r \sim 1$  and  $K \sim 0$ ) an observer with poor distance perception using a large unit in his measurements assesses the size as relatively small. It is suggested that  $C$  by its proportion to  $R$  establishes a unit of visual measurements which is recalibrated for every phenomenological distance in a system characteristic for an individual observer.

An important feature of this system is that it is expressed in terms of the body size of the observer. This permits a departure from the relativity of the subjective comparisons and allows the assignment of a physical magnitude to a subjective assessment. If, for a distant object of size  $T$ , we were to write,

$$T = nR = nC f(r) \sim nC \cosh r$$

then, in the subjective counterparts of these terms, the proportion ( $n$ ) would not necessarily be affected by the observer's system of measurements, that is, this proportion is most likely to be independent of the observer's personal constants,  $K$ , and the values characteristic for him of  $r$  and  $C$  for great distances. The critical condition required to estimate  $T$  correctly, however, is that the observer must place himself ( $R$ ) and the object ( $T$ ) at the same phenomenological distance ( $r$ ) in his system, and that he must allow for the proportion ( $n$ ). This, it is suggested, is a function of effective kinaesthetic activation in the whole body as well as in the eye orbits.

In an actual experiment which was carried out from an attic window with a wide view, twenty observers were asked to imagine that they were swimming through the air towards distant buildings, or climbing their walls. (Slight muscular exercises designed to promote the kinaesthetic activation within the limbs and the eye orbits were alternated with the tasks.) During certain trials each observer was asked to imagine himself clinging to the face of a chimney (9.5 ft. wide and 130 yd. distant), and to say whether his hands would grip the edges of the chimney or whether they would miss them and by how much, that is, by a hand, by a forearm or by an arm. Each observer was also asked to imagine himself climbing across the width of the Post Office Tower (52 ft. wide and 660 yd. distant) and to say how many times he would have to shift his body with extended arms across the face of the tower while doing so. Afterwards the observers were asked to estimate visually the size of the chimney and of the tower in terms of feet or yards. They also estimated the size of their body members. Finally, the anthropometric measurements of the observer's body were taken.

The results showed that the estimates based on the imaginary tasks and on the observers' size given anthropometrically were better than the visual estimates by a highly significant amount ( $P=0.0006$  in the case of the chimney, and  $P=0.002$  in the case of the tower). The visuo-kinaesthetic estimates were remarkably accurate in the case of several observers and, as expected, they depended neither on their perception of distance nor on  $K$ . They were also independent of an observer's knowledge of the dimensions of his body. Such proprioceptive sensitivity (probably connected with a motor type of imagery and with former visuo-motor experience) would be an advantage in survival tests, as, for instance, in space research. Its neuro-physiological mechanism (which may be linked with the activity of the muscle spindles) and its ties with the visual parameters are a matter for further investigation.

The apparatus for this investigation has been designed by Mr. J. W. Chambers and made in this department by Mr. R. J. Sloan and Mr. C. McManus. I am grateful to the Central Research Fund of the University of London for some parts of equipment, and to my colleague, Dr. Sheila Jones, for helpful suggestions.

## FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

## Wednesday, March 29

INSTITUTE OF NAVIGATION (at the Royal Institution of Naval Architects, 10 Upper Belgrave Street, London, S.W.1), at 2.15 p.m.—Meeting on "Performance of Airborne Inertial Navigation Systems".

## Wednesday, March 29—Saturday, April 1

MATHEMATICAL ASSOCIATION (at the Welsh College of Advanced Technology, Cardiff)—Annual General Meeting.

## Thursday, March 30

ROYAL SOCIETY OF ARTS, COMMONWEALTH SECTION (at John Adam Street, Adelphi, London, W.C.2), at 5.15 p.m.—Mr. John Karefa-Smart: "The Problems of Nutrition in Developing Countries".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. E. T. Norris: "Loading of Power Transformers".

INSTITUTION OF STRUCTURAL ENGINEERS (at 11 Upper Belgrave Street, London, S.W.1), at 6 p.m.—Mr. W. I. J. Price: "Expansion Joints for Bridges and Over-Head Highways".

SOCIETY OF INSTRUMENT TECHNOLOGY (at the Stanley Palace, Watergate Street, Chester), at 7.30 p.m.—Mr. A. L. Rankin: "Lasers".

## Thursday, March 30—Friday, March 31

LUTON COLLEGE OF TECHNOLOGY, DEPARTMENT OF SCIENCE (at Park Square, Luton)—Symposium on "The Biochemistry and Genetics of Macromolecules".

## Friday, March 31

BRITISH COMPUTER SOCIETY (in the Mechanical Engineering Department, Imperial College of Science and Technology, London, S.W.7)—Symposium on "The Computer Service Bureau in Business and Commerce".

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 9.15 a.m.—Conference on "New Methods of Increasing Productivity in the Rubber Industry".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. R. W. Stevens: "Acoustic Behaviour of Materials".

## Sunday, April 2—Thursday, April 6

ROYAL COLLEGE OF SURGEONS OF ENGLAND (in association with The Royal Society; The Royal College of Surgeons of Edinburgh; The University of Edinburgh; The University of Glasgow; The University of London; University College Hospital; King's College Hospital; The Lister Institute of Preventive Medicine; The Wellcome Trust; and The Ciba Foundation, at the Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2)—Lister Centenary Conference.

## Monday, April 3

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Mr. Norman D. C. Hammond: "Exploring Ancient Seistan".

## APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURER or LECTURER in the DEPARTMENT OF APPLIED MATHEMATICS and MATHEMATICAL PHYSICS—The Registrar, University College of South Wales and Monmouthshire, Cardiff (March 28).

LECTURERS and ASSISTANT LECTURERS (with a good honours degree in physiology, biochemistry or related subjects, or with medical qualifications registrable in the United Kingdom) in PHYSIOLOGY—The Registrar, The University, Manchester, quoting Ref. No. 32/67/Na (March 31).

LECTURER (with experience in electronics, electronic physics or plasma physics) in the DEPARTMENT OF PHYSICS—The Registrar, University College of Wales, Aberystwyth (April 3).

ASSISTANT LECTURER (with an interest in extractive or chemical metallurgy) in METALLURGY—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (April 7).

LECTURER or ASSISTANT LECTURER in BIOCHEMISTRY; and a LECTURER or ASSISTANT LECTURER in FOOD SCIENCE in the DEPARTMENT OF BIOCHEMISTRY, NUTRITION and FOOD SCIENCE, University of Ghana—The Assistant Registrar, Universities of Ghana Office, 15 Gordon Square, London, W.C.1; or The Registrar, University of Ghana, P.O. Box 25, Legon, Accra, Ghana (April 7).

LECTURERS or ASSISTANT LECTURERS in the DEPARTMENT OF BOTANY (one appointment will be made for teaching and research in biochemical genetics and/or plant metabolism)—The Registrar, University Senate House, Bristol 2 (April 7).

ASSISTANT (with an honours degree in botany, some subsequent research experience, and preferably an interest in plant morphology or morphogenesis) in BOTANY—The Secretary of the University Court, The University, Glasgow (April 8).

STATISTICIAN (with a Ph.D. degree in arts or science with mathematics and mathematical statistics as major subjects, or with postgraduate research experience of equivalent standard and duration supported by satisfactory evidence of research ability) in the DIVISION OF MATHEMATICAL STATISTICS, COMMONWEALTH SCIENTIFIC and INDUSTRIAL RESEARCH ORGANIZATION, AUSTRALIA, to take part in the respective Divisional research programmes of the Division of Protein Chemistry and the Division of Animal Health (Animal Health Research Laboratory) which are closely located in Melbourne—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 440/195 (April 14).

LECTURER (with an honours degree in physiology or in a closely related subject, or medically qualified) in PHYSIOLOGY—The Secretary, Queen's College, Dundee (April 15).

LECTURERS/ASSISTANT LECTURERS in ZOOLOGY—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3 (April 15).

SECOND CHAIR OF PURE MATHEMATICS—The Registrar, The University, Sheffield (April 15).

CHAIR OF CHEMICAL PATHOLOGY at University College Hospital Medical School—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 17).

SENIOR ASSISTANT LIBRARIAN (with a degree and experience of dealing with scientific material, and preferably professional qualifications)—The Secretary, Royal Holloway College (University of London), Englefield Green, Surrey (April 18).

PROFESSOR OF PHARMACOLOGY, and a PROFESSOR OF PHARMACEUTICS at the University of Khartoum—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (April 20).

LECTURER and an ASSISTANT LECTURER in PHYSIOLOGY—Secretary of the University Court, The University, Glasgow (April 21).

CHAIR OF PHARMACEUTICS at Chelsea College of Science and Technology—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 24).

DEMONSTRATOR in PATHOLOGY—The Registrar, The University, Bristol (April 24).

DEMONSTRATOR in PSYCHOLOGY—The Registrar, The University, Liverpool, quoting Ref. RV/420 (April 29).

LECTURERS/ASSISTANT LECTURERS (preferably interested in microbiology, mycology, algology, immunochimistry, genetics, parasitology, vertebrate physiology, fish ecology, higher plant botany, ornithology) in the DEPARTMENT OF BIOLOGY—The Secretary, Royal College of Advanced Technology, Salford 5, quoting Ref. No. B/6 (May 1).

EXPERIMENTAL OFFICER (qualified mechanical engineer) in the DEPARTMENT OF MECHANICAL ENGINEERING to assist in a programme of research connected with the study of turbine and compressor blade vibration—The Staff Officer, University of Surrey, Battersea Park Road, London, S.W.11.

LECTURER or ASSISTANT LECTURER in PHARMACOLOGY in the Postgraduate and Undergraduate School of Studies in Pharmacy—The Registrar, University of Bradford, Bradford 7, Yorkshire.

MASTER to teach PHYSICS at all levels—The Headmaster, School House, Rugby.

PHYSICAL CHEMIST for an S.R.C. supported research project on biological fuel cells—Prof. P. N. Rowe, Department of Chemical Engineering, University College London, Gower Street, London, W.C.1.

REGISTRAR (graduate with administrative experience of a high order)—The Secretary, Imperial College of Science and Technology, London, S.W.7.

RESEARCH FELLOW at the Institute of Sound and Vibration Research for a fundamental study of community response to noise from machinery—The Deputy Secretary, The University, Southampton.

RESEARCH FELLOW with research experience in astronomy, optics, spectroscopy or plasma physics) in a Science Research Council supported research group undertaking high resolution solar spectroscopy from rocket and satellite vehicles—Prof. D. J. Bradley, Department of Pure and Applied Physics, Queen's University, Belfast, Northern Ireland.

SENIOR TECHNICIAN (with experience of work in a research or teaching laboratory, able to make up and maintain electrical equipment, and an interest in instruments) in the DEPARTMENT OF ZOOLOGY—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh.

# MICROMANIPULATORS

*if you use a*

**MICROSCOPE**

*you need a*

**SINGER**

FULLY PATENTED

**MICROMANIPULATOR**

Singer micromanipulators are used in most laboratories all over the world. Three types available:

Mk I Low power for magnifications  $\times 1$  to  $\times 200$

Mk II For magnifications  $\times 1$  to  $\times 500$

Mk III High power for magnifications  $\times 100$  to  $\times 1,000$  plus

The most advanced instruments for micromanipulation. As described by Barer and Saunders-Singer with further improvements.

Full details and demonstrations upon request to:

**SINGER INSTRUMENT CO. LTD.,**  
Fountain Court, 83 London St.,  
Reading, Berkshire, England.

## HEATHWAY FOR GLASS WORKING LATHES

*Latest design 'S' type lathe*

All the HEATHWAY range of lathes have the following features

- ★ Robust construction and lasting accuracy
- ★ Efficient variable speed and easily accessible controls
- ★ Smooth traverses essential to good glassworking

*May we send you details of our range of lathes and equipment*

Write or phone:

**The HEATHWAY MACHINERY CO., LTD.,**  
UXBRIDGE ROAD, HILLINGDON, MIDDXX.  
TEL. UXB 36345/6

# DM23

**...newest addition  
to the famous  
Meopta range...**

The Meopta DM 23 offers working distance up to 200mm... and is typical of the superb workmanship, the reliability and the versatility for which the Meopta D range have justly become famous. The DM 23 can be supplied with a wide range of interchangeable parts—and full technical details will be supplied on request.

### Classified Advertisements

Semi-displayed £4 16s. per single column inch. Minimum £2, each additional 1/12th of an inch 8s. Full page £132. Half page across £66. Colour (orange) £15 extra. 1s. is charged for the re-direction of replies to advertisements with a box number.

ADVERTISEMENTS SHOULD BE ADDRESSED TO: T. G. Scott and Son, Limited, 1 Clement's Inn, Strand, London, W.C.2. Telephone: 01-405 4743. Telegrams: Textualist, London, W.C.2.

### APPOINTMENTS VACANT

#### UNIVERSITY OF ASTON IN BIRMINGHAM DEPARTMENT OF CHEMISTRY RESEARCH IN CHEMISTRY

Applications are invited from graduates and those who will be graduating this year for Research Assistantships and Research Studentships. Areas of research preferred include: Chemistry and Biosynthesis of Natural Products, Inorganic Complexes, Infra-red Spectroscopy, Synthesis and Crystallisation of Polymers, Organo-Silicon Chemistry, Flammability of Plastics, High Temperature Ionization, Stabilities of Negative Ions, but other fields will be considered where applicants are suitably qualified. Salaries for Research Assistants will be within the scale £680 to £1,080 per annum, depending upon qualifications and experience, whilst grants for Research Students are usually £500 per annum (plus fees), which may be augmented by demonstrating. Applicants should normally possess a good Honours Degree or its equivalent. Successful applicants may register for a higher degree.

Further information and application forms may be obtained from the Administrative Assistant, Department of Chemistry, The University of Aston in Birmingham, Gosta Green, Birmingham 4. Please quote: 541/6. (1274)

#### UNIVERSITY OF SURREY DEPARTMENT OF MECHANICAL ENGINEERING

Applications are invited from qualified mechanical engineers for an EXPERIMENTAL OFFICER to assist in a programme of research work connected with the study of turbine and compressor blade vibration. The equipment includes a high-speed rotating test rig designed to run up to speeds of 20,000 r.p.m. and the work is supported by a grant from the Science Research Council.

The salary is within the range of £1,400 by £75 (2) to £1,550 plus £60 London Allowance per annum.

The Department of Mechanical Engineering is scheduled to move to the new University site at Guildford in 1968.

Applications, together with the names and addresses of three referees, should be sent to the Staff Officer, University of Surrey, Battersea Park Road, London, S.W.11. (1310)

#### SIX BIOLOGISTS

Duties: 1. Lecture to undergraduate students in (a) general biology; (b) one of the following areas of specialization: fisheries and/or wildlife biology, radiation biology, cellular biology, forestry, marine biology, etc.

Experience: 1. A proven history in research. 2. Past experience in lecturing an asset.

Rank and Salary: The appointments will be made at salaries according to academic training and experience. The minimum salary, however, will usually be about \$10,000.

Date of Appointment: The initial appointment will be made in July of this year.

Inquiries to: Professor K. Ronald, Head, Department of Zoology, University of Guelph, Guelph, Ontario, Canada. (1112)

#### NORTH LONDON BLOOD TRANSFUSION CENTRE

DEANSBROOK ROAD, EDGWARE, MIDDLESEX

Principal Scientific Officer to be in overall charge of Laboratories. Must have a good working knowledge of blood group serology and transfusion technology and a higher degree is essential. Ample opportunities for research. Whitley Council conditions and salary.

Apply in writing to Director. (1217)

App. Chem.

**CSIRO**  
**AUSTRALIA**

DIVISION OF COAL RESEARCH

## INORGANIC OR PHYSICAL CHEMIST

Applications are invited for appointment as Research Scientist or Senior Research Scientist (Inorganic or Physical Chemistry) with the Organization's Division of Coal Research, located at North Ryde, Sydney, N.S.W.

Part of the Division's research programme is concerned with the production of industrial carbons and graphites from indigenous carbonaceous fuels. The Division is well equipped with a wide range of modern instrumental techniques, including: X-ray diffraction, optical and electron microscopy, high-temperature/high-pressure equipment, and equipment for the measurement of electrical properties.

The appointee will be required to carry out research on the formation, structure and properties of ordered or crystalline forms of carbon; this would include research into the development of graphitic structures at relatively low temperatures and the catalysis of graphitization.

Applicants should have a Ph.D. degree in Inorganic or Physical Chemistry or have had postgraduate research experience of equivalent standard and duration supported by satisfactory evidence of research ability. Some experience in higher temperature research such as molten salt reactions would be desirable.

**SALARY:** Depending upon qualifications and experience within the salary ranges of: \$A5,198-\$A6,570 p.a. or \$A6,840-\$A7,922 p.a.

Salary rates for women are \$A428 p.a. less than the corresponding rates for men.

Promotion within CSIRO to a higher classification is determined by merit.

The duration of the appointment will be determined in consultation with the successful candidate; some applicants may prefer a fixed term appointment for three years, in which case consideration will be given to the continuation of F.S.S.U. arrangements.

Fares paid for the appointee and his dependent family. If the appointee is at present permanently domiciled outside Australia, return fares will be paid at the conclusion of a fixed term appointment. Further particulars supplied on application to:

Mr. R. F. Turnbull, Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2,

to whom applications (quoting Appointment No.: 480/538) should be addressed by the 21st April, 1967. (1366)

A.E.R.E. HARWELL

## A Toxicologist

is required for research on the possible toxicity of food after its treatment with ionizing radiation for preservation or other purposes.

He will be expected to take charge of an established animal house where chronic toxic tests are in progress with rats and mice. The work is supported by the service of experienced technicians and excellent laboratory facilities are available for histological and other investigations. The services of a consultant histopathologist are available as required.

The successful candidate will take up his duties at the Wantage Research Laboratory which is an integral part of the Atomic Energy Research Establishment at Harwell.

Applicants should have a first or good second class honours degree in an appropriate field and have some previous experience of work with experimental animals.

Starting salary will be within the range £995 to £2,310 depending on qualifications and experience. A house or assistance in house purchasing will be available for married officers living beyond daily travelling distance.

For further details and application forms, please write to:

Personnel Department A, 518234,  
Atomic Energy Research Establishment,  
Harwell, Didcot, Berkshire.

(1315)
